Reader's Guide

The Reader's Guide is provided to assist readers in locating articles on related topics. It classifies articles into 31 general topical categories: Bayesian Statistics; Descriptive Statistics; Distributions; Graphical Displays of Data; Hypothesis Testing; Important Publications; Inferential Statistics; Item Response Theory; Mathematical Concepts; Measurement Concepts; Organizations; Publishing; Qualitative Research; Reliability of Scores; Research Design Concepts; Research Designs; Research Ethics; Research Process; Research Validity Issues; Sampling; Scaling; Social Network Analysis; Software Applications; Statistical Assumptions; Statistical Concepts; Statistical Procedures; Statistical Tests; Structural Equation Modeling; Theories, Laws, and Principles; Types of Variables; and Validity of Scores. Entries may be listed under more than one topic.

Bayesian Statistics

Bayes's Theorem
Bayesian Adaptive Randomization Design
Bayesian Data Analysis
Bayesian Information Criterion
Bayesian Network Analysis
Posterior Distribution

Descriptive Statistics

Central Tendency, Measures of
Cohen's d Statistic
Cohen's f Statistic
Correspondence Analysis
Descriptive Statistics
Effect Size, Measures of
Eta-Squared
Factor Loadings
Mean
Median

About the Editor

Bruce B. Frey, PhD, is an award-winning teacher and scholar at the University of Kansas. He has authored more than 100 research articles and papers. Among his books are the best-selling textbook, *Statistics for People Who (Think They) Hate Statistics*, *Modern Classroom Assessment*, and *There's a Stat for That!*, all

published by SAGE, and *Stat Hacks* published by O'Reilly. He is the editor of *The SAGE Encyclopedia of Educational Research, Measurement, and Evaluation*. In his free time, he celebrates bubblegum pop music of the late 1960s on his popular podcast, *Echo Valley*.

Introduction

The *SAGE Encyclopedia of Research Design, 2nd Edition*, is a pretty big advance over the original edition, published in 2010. And that first edition was pretty good. (He said, not mentioning that he was a co-editor of that work). That original edition had a little more than 500 entries and covered an impressively wide range of topics in research design. As editor Neil Salkind wrote in his introduction, the entries were “written by scholars in the field of research design, the discipline of how to plan and conduct empirical research, including the use of both quantitative and qualitative methods. A simple review of the Reader’s Guide shows how broad the field is, including such topics as descriptive statistics, a review of important mathematical concepts, a description and discussion of the importance of such professional organizations as the American Educational Research Association and the American Statistical Association, the role of ethics in research, important inferential procedures, and much more.”

This is all true of the second edition, but there are now more than 650 entries! That increase of 30% over the first edition means several things.

- First, there are now four volumes, not three.
- Second, I have the space to dig even deeper into the qualitative world of social science research, adding dozens of new entries.
- Third, we have more coverage of advanced statistical analyses, research ethics, and less common research designs, with many new entries about social network analysis, human subjects research, single-subject design, and sampling techniques, for example.
- Fourth, we now cover more contemporary “hot” topics that were barely mentioned or completely missing from the first edition, such as Bayesian statistics, data mining, graphing theory, and machine learning.

So, adding new entries that were not in the first edition was one way to improve the encyclopedia. But the improvements didn’t stop there. Almost 200 of the original entries were revised or rewritten. To be more

precise, 34% of the entries that were brought along from the original edition were updated (by the original authors in most cases). Ultimately, more than half of this encyclopedia that you, metaphorically speaking, hold in your hand is new!

How to Make a Second Edition of an Encyclopedia

As an existing encyclopedia, we had a list of entries (or *headwords*) with which to start. To decide which headwords to include, I recruited a super team of experts in various areas of research design, the Editorial Advisory Board. As a group, we reviewed the list. Several decisions had to be made:

1. Should any headwords be removed? There weren’t really many headwords from the first edition to remove; it wasn’t like we were worried that there would be too much useful information and we’d better make it smaller. But, there were a few cases where we thought to combine some entries or reorganize things based on new entries we knew would be created.
2. Which existing entries should be revised? Things change, time moves on, and we learn new stuff all the time in science. So, in the decade since publication (really 15 years or so in terms of when the writing actually happened), we know more about structural equation modeling or the ethics of human subjects research or how to do surveys on the internet. In addition to updating the content of an entry, the Further Readings sections needed some freshening up.
3. What headwords should be added? One value of having a team of experts, the Board, but also an experienced group of SAGE developmental editors, who have worked on other scholarly encyclopedias and hundreds of scholarly publications, is that there’s a sense of what is new in research methods and, also, what isn’t on this list that *needs* to be. They all suggested new headwords for this edition. Ultimately, 163 brand new headwords were identified. Once the list of entries was finalized, we assigned each one a

specific length of 500, 1,000, 2,000, or 3,000 words. This decision was based on the importance of the topic and how many words we thought would be necessary to explain stuff well.

The final step was to identify authors for each of the new or revised entries. We used a variety of mechanisms, including asking advisory board members to identify scholars who were experts in a particular area; consulting professional journals, books, conference presentations, and other sources to identify authors familiar with a particular topic; and drawing on the personal contacts that the editorial board members have cultivated over many years of working in this field. In the case of revised entries, the original authors were usually recruited to update their work. Once authors were confirmed, they were given explicit directions and deadlines for completing and submitting their entry. As the entries were submitted, the developmental editor and I read them and, if necessary, requested both format and substantive changes. Once a revised entry was resubmitted, it was once again reviewed and, when acceptable, passed on to production. Notably, most entries were acceptable on initial submission.

How to Use the SAGE Encyclopedia of Research Design, 2nd Edition

The *SAGE Encyclopedia of Research Design, 2nd Edition*, is a collection of entries intended for the naive, but educated, consumer. It is a reference tool for users who may be interested in learning more about a particular research technique (such as “control group” or “member check”).

Users can search the encyclopedia for specific information or browse the Reader’s Guide to find topics of interest. All the headwords are sorted into topic areas, so readers can quickly focus on where they want to go. For example, if you want to learn more about how measurement works, but aren’t sure exactly what the relevant terms are, browse the entries that are from that world—like Standardized Score or Ceiling Effect under the Measurement Concepts category—and you will get pointed in the right direction. For readers who want to pursue a topic further, each entry ends with both a list of related entries in the encyclopedia and a set of further readings in the literature, often including online sources. The further readings not only include important recent publications but also key classic writings from the past.

Acknowledgments

I have had the privilege of working on many projects with SAGE and the folks there are remarkable. It’s a lot of work to manage and edit hundreds of entries and, tougher still, to wrangle and organize hundreds of authors! (And most of these authors are academic-types, college professors like me who are notoriously difficult to keep focused.) For this project, it started with Andrew Boney, the acquisitions editor. He had the bright idea that a second edition was needed for the *Encyclopedia of Research Design* and brought us all together initially. The boss for this project who is most responsible for keeping things on track and making my work and all the contributing authors’ work better was Shirin Parsavand, the developmental editor. My name is on the cover, but this is Shirin’s encyclopedia as much as it is mine. Carole Maurer, developmental editor for the first edition, helped move us across the finish line. Tamara Tanso, assistant editor, and so easy with which to work. The sophisticated online software system that allows for smooth collaboration on a massive project like this is maintained by Letty Gutierrez. She was very nice to me when I had questions.

The Editorial Advisory Board was made up of Neal Kingston, Phil Gallagher, and Chris Niileksela, my colleagues at the University of Kansas, and Rebecca Woodland at the University of Massachusetts. Look those names up on Google Scholar and you’ll see how much wisdom they brought to this project. Thank you, my super team.

Of course, the hundreds of scholars who took the time to share their expertise deserve a special emphasis. If you review the list of contributors in the front of the first volume, I guarantee you’ll recognize more than one name whose research you are familiar with. They wrote this encyclopedia and I am sincerely grateful.

In my personal life, I’d like to thank my wife, Bonnie Johnson, for her support as I worked on this project almost every day for a couple years. Much of that time was during COVID, so we were together a lot and she had many opportunities to tire of me and my interest in engaging her in conversation about dilemmas like whether to call an entry *Cronbach’s alpha* or *coefficient alpha* and whether the coefficient itself is an estimate of reliability or just internal consistency and what the heck is the difference between the two and does it matter. Thanks, Bonnie!

A PRIORI MONTE CARLO SIMULATION

An a priori Monte Carlo simulation is a special case of a Monte Carlo simulation that is used in the design of a research study, generally when analytic methods do not exist for the goal of interest for the specified model or are not convenient. A Monte Carlo simulation is generally used to evaluate empirical properties of some quantitative method by generating random data from a population with known properties, fitting a particular model to the generated data, collecting relevant information of interest, and replicating the entire procedure a large number of times (e.g., 10,000). In an a priori Monte Carlo simulation study, interest is generally in the effect of design factors on the inferences that can be made rather than a general attempt at describing the empirical properties of some quantitative method. Three common categories of design factors used in a priori Monte Carlo simulations are sample size, model misspecification, and unsatisfactory data conditions. As with Monte Carlo methods in general, the computational tediousness of a priori Monte Carlo simulation methods essentially requires one or more computers because of the large number of replications and thus the heavy computational load. Computational loads can be very great when the a priori Monte Carlo simulation is implemented for methods that are themselves computationally tedious (e.g., bootstrap, multilevel models, and Markov chain Monte Carlo methods).

For an example of when an a priori Monte Carlo simulation study would be useful, Ken Kelley and Scott Maxwell have discussed sample size planning for multiple regression when interest is in sufficiently narrow confidence intervals for standardized regression

coefficients (i.e., the accuracy-in-parameter-estimation approach to sample size planning). Confidence intervals based on noncentral t distributions should be used for standardized regression coefficients. Currently, there is no analytic way to plan for the sample size so that the computed interval will be no larger than desired some specified percent of the time. However, Kelley and Maxwell suggested an a priori Monte Carlo simulation procedure when random data from the situation of interest are generated and a systematic search (e.g., a sequence) of different sample sizes is used until the minimum sample size is found at which the specified goal is satisfied.

As another example of when an application of a Monte Carlo simulation study would be useful, Linda Muthén and Bengt Muthén have discussed a general approach to planning appropriate sample size in a confirmatory factor analysis and structural equation modeling context by using an a priori Monte Carlo simulation study. In addition to models in which all the assumptions are satisfied, Muthén and Muthén suggested sample size planning using a priori Monte Carlo simulation methods when data are missing and when data are not normal—two conditions most sample size planning methods do not address.

Even when analytic methods do exist for designing studies, sensitivity analyses can be implemented within an a priori Monte Carlo simulation framework. Sensitivity analyses in an a priori Monte Carlo simulation study allow the effect of misspecified parameters, misspecified models, and/or the validity of the assumptions on which the method is based to be evaluated. The generality the a priori Monte Carlo simulation studies is its biggest advantage. As Maxwell, Kelley, and Joseph Rausch have stated, “Sample size can be planned for any research goal, on any statistical technique, in any

situation with an a priori Monte Carlo simulation study” (2008, p. 553).

ABSTRACT

An abstract is a summary of a research or a review article and includes critical information, including a complete reference to the work, its purpose, methods used, conclusions reached, and implications. For example, here is one such abstract from the *Journal of Black Psychology* authored by Timo Wandert from the University of Mainz, published in 2009 and titled “Black German Identities: Validating the Multidimensional Inventory of Black Identity.”

All the previously-mentioned elements are included in this abstract: the purpose, a brief review of important ideas to put the purpose into a context, the methods, the results, and the implications of the results.

This study examines the reliability and validity of a German version of the Multidimensional Inventory of Black Identity (MIBI) in a sample of 170 Black Germans. The internal consistencies of all subscales are at least moderate. The factorial structure of the MIBI, as assessed by principal component analysis, corresponds to a high degree to the supposed underlying dimensional structure. Construct validity was

examined by analyzing (a) the intercorrelations of the MIBI subscales and (b) the correlations of the subscales with external variables. Predictive validity was assessed by analyzing the correlations of three MIBI subscales with the level of intra-racial contact. All but one prediction concerning the correlations of the subscales could be confirmed, suggesting high validity. No statistically significant negative association was observed between the Black nationalist and assimilationist ideology subscales. This result is discussed as a consequence of the specific social context Black Germans live in and is not considered to lower the MIBI’s validity. Observed differences in mean scores to earlier studies of African American racial identity are also discussed.

Abstracts serve several purposes. First, they provide a quick summary of the complete publication that is easily accessible in the print form of the article or through electronic means. Second, they become the target for search tools and often provide an initial screening when a researcher is doing a literature review. It is for this reason that article titles and abstracts contain key words that one would look for when searching for such information. Third, they become the content of reviews or collections of abstracts such as PsycINFO, published by the American Psychological Association (APA). Finally, abstracts sometimes are used as stand-ins for the actual papers when there are time or space limitations, such as at professional meetings. In this instance, abstracts are usually presented as posters in presentation sessions.

Most scholarly publications have very clear guidelines as to how abstracts are to be created, prepared, and used. For example, the APA, in the *Publication Manual of the American Psychological Association*, provides information regarding the elements of a good abstract and suggestions for creating one. While guidelines for abstracts of scholarly publications (such as print and electronic journals) tend to differ in the specifics, the following four guidelines apply generally:

1. The abstract should be short. For example, APA limits abstracts to 250 words, and MEDLINE limits them to no more than 400 words. The abstract should be submitted as a separate page.
2. The abstract should appear as one unindented paragraph.
3. The abstract should begin with an introduction and then move to a very brief summary of the method, results, and discussion.

4. After the abstract, five related keywords should be listed. These keywords help make electronic searches efficient and successful.

With the advent of electronic means of creating and sharing abstracts, visual and graphical abstracts have become popular, especially in disciplines in which they contribute to greater understanding by the reader.

ACCURACY IN PARAMETER ESTIMATION

Accuracy in parameter estimation (AIPE) is an approach to sample size planning concerned with obtaining narrow confidence intervals. The standard AIPE approach yields the necessary sample size so that the expected width of a confidence interval will be sufficiently narrow. Because confidence interval width is a random variable based on data, the actual confidence interval will almost certainly be wider or narrower than the expected confidence interval width. A modified AIPE approach allows sample size to be planned so that there will be some desired degree of assurance that the observed confidence interval will be sufficiently narrow.

AIPE and modified AIPE are “fixed N ” procedures, in that one needs to specify parameters in order to find the sample size, which is then a fixed value. A new version of AIPE, termed sequential AIPE, is not a fixed N procedure but rather is sequential, where sampling of cases continues until a stopping rule is satisfied. Whereas the standard AIPE approach addresses questions such as “what size sample is necessary so that the expected width of the 95% confidence interval width will be no larger than ω ,” where ω is the desired

confidence interval width, the modified AIPE approach addresses questions such as “what size sample is necessary so that there is γ 100% assurance that the 95% confidence interval width will be no larger than ω ,” where γ is the desired value of the assurance parameter. Furthermore, sequential AIPE does not ask “What size sample is necessary?” but rather “Is the accuracy of the estimate sufficient for sampling to stop?” This entry further discusses the importance of confidence interval width, the origins and goals of the AIPE approach, and the subsequent development of the sequential AIPE approach.

Confidence interval width is a way to operationalize the accuracy of the parameter estimate, holding everything else constant. Provided appropriate assumptions are met, a confidence interval consists of a set of plausible parameter values obtained from applying the confidence interval procedure to data, where the procedure yields intervals such that $(1 - \alpha)$ 100% will correctly bracket the population parameter of interest, where $1 - \alpha$ is the desired confidence interval coverage. Holding everything else constant, as the width of the confidence interval decreases, the range of plausible parameter values is narrowed and thus more values can be excluded as implausible values for the parameter. In general, whenever a parameter value is of interest, not only should the point estimate itself be reported, but so too should the corresponding confidence interval for the parameter, as it is known that a point estimate almost certainly differs from the population value and does not give an indication of the degree of uncertainty with which the parameter has been estimated. Wide confidence intervals, which illustrate the uncertainty with which the parameter has been estimated, are generally undesirable. Because the direction, magnitude, and accuracy of an effect can be simultaneously evaluated with confidence intervals, planning a research study in an effort to obtain narrow confidence intervals is considered an ideal way to improve research findings and increase the cumulative knowledge of a discipline.

Operationalizing accuracy as the observed confidence interval width is not new. In fact, Jerzy Neyman (1937) used the confidence interval width as a measure of accuracy in his seminal work on the theory of confidence intervals: “the accuracy of estimation corresponding to a fixed value of $1 - \alpha$ may be measured by the length of the confidence interval” (p. 358; notation changed to reflect current usage). Statistically, accuracy is defined as the square root of the mean square error, which is a function of precision and bias. When the bias is zero, accuracy and precision are equivalent concepts.

The accuracy in parameter estimation approach is so named because its goal is to improve the overall accuracy of estimates and not just the precision or bias alone. Precision can often be improved at the expense of bias, which may or may not improve the accuracy. Thus, to not obtain estimates that are sufficiently precise but possibly more biased, the (sequential) AIPE approach sets its goal as obtaining sufficiently accurate parameter estimates as operationalized by the width of the corresponding $(1 - \alpha)$ 100% confidence interval.

Research studies are often undertaken with the goal of basing important decisions on the results. However, when an effect has a corresponding confidence interval that is wide, decisions based on such effect sizes need to be used with caution. A point estimate can be impressive according to some standard, but for the confidence limits to illustrate that the estimate is not very accurate. For example, a commonly used set of guidelines for the standardized mean difference in the behavioral, educational, and social sciences is that population standardized effect sizes of 0.2, 0.5, and 0.8 are regarded as “small,” “medium,” and “large” effects, respectively (Cohen, 1969, 1988). Suppose that the population standardized mean difference is thought to be medium (i.e., 0.50) based on an existing theory and a review of the relevant literature. Further suppose that a researcher planned a sample size so that there would be a statistical power of .80 when the Type I error rate is set to .05, which yields a necessary sample size of 64 participants per group (128 total). In such a situation, supposing that the observed standardized mean difference was in fact exactly 0.50, the 95% confidence interval has a lower and upper limit of .147 and .851, respectively. Thus, the lower confidence limit is smaller than “small” and the upper confidence limit is larger than “large.” Although there was enough statistical power (recall sample size was planned so that power = .80 and indeed the null hypothesis of no group mean difference rejected, $p = .005$), in this case sample size was not sufficient from an accuracy perspective, as illustrated by the wide confidence interval.

Historically, confidence intervals were not often reported in applied research in the behavioral, educational, and social sciences, as well as in many other domains. Jacob Cohen (1994) once suggested researchers failed to report confidence intervals because their widths were “embarrassingly large” (p. 1002). In an effort to plan sample size so as to not obtain confidence intervals that are embarrassingly large, and in fact to plan sample size so that confidence intervals are sufficiently narrow, the (sequential) AIPE approach should be considered. The argument for planning sample size from an AIPE perspective or using sequential AIPE, in which sample size is not literally planned, but sampling

continues until a stopping rule is satisfied, is due to the desire to report point estimates and confidence intervals instead of or in addition to the results of null hypothesis significance tests. This paradigmatic shift has led to (sequential) AIPE approaches to sample size planning becoming more useful than was previously the case, given the emphasis now placed on confidence intervals instead of focusing solely on the results of null hypothesis significance tests.

Whereas the power analytic approach to sample size planning has as its goal rejecting a false null hypothesis with some specified probability, the (sequential) AIPE approach is not concerned with whether or not some specified null value can be rejected (i.e., is the null value outside of the confidence interval limits), making it a fundamentally different approach than the power analytic approach. Not surprisingly, the (sequential) AIPE and power analytic approaches can suggest very different values for sample size, depending on the particular goals (e.g., desired width or desired power) specified. The (sequential) AIPE approach to sample size planning is able to simultaneously consider the direction of an effect (which is what the null hypothesis significance test provides), its magnitude (“best” and “worst” case scenarios based on the values of the confidence limits), and the accuracy with which the population parameter was estimated (via the width of the confidence interval).

Ken Kelley and Scott Maxwell first used the term “accuracy in parameter estimation” (and the acronym AIPE) as a general framework in a 2003 article where they argued for its widespread use in lieu of or in addition to the power analytic approach. However, the general idea of AIPE has appeared in the literature sporadically since at least the 1960s. In a 2000 article, James Algina and Stephen Olejnik discussed a similar approach with the goal of an estimate sufficiently close to its corresponding population value, while in 2003, Michael Jiroutek and colleagues proposed a method to simultaneously have a sufficient degree of power and confidence interval narrowness. As of 2020, the most extensive program for planning sample size from the (sequential) AIPE perspective is R (R Core Developmental Team) using the MBESS package.

ACTION RESEARCH

Action research differs from conventional research methods in three fundamental ways. First, its primary goal is social change. Second, members of the study sample accept responsibility for helping resolve issues that are the focus of the inquiry. Third, relationships between researcher and study participants are more complex and less hierarchical. Most often, action research is viewed as a process of linking theory and practice in which scholar-practitioners explore a social situation by posing a question, collecting data, and testing a hypothesis through several cycles of action. The most common purpose of action research is to guide practitioners as they seek to uncover answers to complex problems in disciplines such as education, health sciences, sociology, or anthropology. Action research is typically underpinned by ideals of social justice and an ethical commitment to improve the quality of life in particular social settings. Accordingly, the goals of action research are as unique to each study as participants' contexts; both determine the type of data-gathering methods that will be used. Because action research can embrace natural *and* social science methods of scholarship, its use is not limited to either positivist or heuristic approaches. It is, as John Dewey

pointed out, an *attitude* of inquiry rather than a single research methodology.

This entry presents a brief history of action research, describes several critical elements of action research, and offers cases for and against the use of action research.

Historical Development

Although not officially credited with authoring the term *action research*, Dewey proposed five phases of inquiry that parallel several of the most commonly used action research processes, including curiosity, intellectualization, hypothesizing, reasoning, and testing hypotheses through action. This recursive process in scientific investigation is essential to most contemporary action research models. The work of Kurt Lewin is often considered seminal in establishing the credibility of action research. In anthropology, William Foote Whyte conducted early inquiry using an action research process similar to Lewin's. In health sciences, Reginald Revans renamed the process *action learning* while observing a process of social action among nurses and coal miners in the United Kingdom. In the area of emancipatory education, Paulo Freire is acknowledged as one of the first to undertake action research characterized by participant engagement in sociopolitical activities.

The hub of the action research movement shifted from North America to the United Kingdom in the late 1960s. Lawrence Stenhouse was instrumental in revitalizing its use among health care practitioners. John Elliott championed a form of educational action research in which the researcher-as-participant takes increased responsibility for individual and collective changes in teaching practice and school improvement. Subsequently, the 1980s were witness to a surge of action research activity centered in Australia. Wilfred Carr and Stephen Kemmis authored *Becoming Critical*, and Kemmis and Robin McTaggart's *The Action Research Planner* informed much educational inquiry. Carl Glickman is often credited with a renewed North American interest in action research in the early 1990s. He advocated action research as a way to examine and implement principles of democratic governance; this interest coincided with an increasing North American appetite for postmodern methodologies such as personal inquiry and biographical narrative.

Characteristics

Reflection

Focused reflection is a key element of most action research models. One activity essential to reflection is referred to as *metacognition*, or thinking about

thinking. Researchers ruminate on the research process even as they are performing the very tasks that have generated the problem and, during their work, derive solutions from an examination of data. Another aspect of reflection is circumspection, or learning-in-practice. Action research practitioners typically proceed through various types of reflection, including those that focus on technical proficiencies, theoretical assumptions, or moral or ethical issues. These stages are also described as learning *for* practice, learning *in* practice, and learning *from* practice. Learning for practice involves the inquiry-based activities of readiness, awareness, and training engaged in collaboratively by the researcher and participants. Learning in practice includes planning and implementing intervention strategies and gathering and making sense of relevant evidence. Learning from practice includes culminating activities and planning future research. Reflection is integral to the habits of thinking inherent in scientific explorations that trigger explicit action for change.

Iterancy

Most action research is cyclical and continuous. The spiraling activities of planning, acting, observing, and reflecting recur during an action research study. Iterancy, as a unique and critical characteristic, can be attributed to Lewin's early conceptualization of action research as involving hypothesizing, planning, fact-finding (reconnaissance), execution, and analysis (see Figure 1).

These iterations comprise internal and external repetition referred to as *learning loops*, during which participants engage in successive cycles of collecting and making sense of data until agreement is reached on appropriate action. The result is some form of human activity or tangible document that is immediately applicable in participants' daily lives and instrumental in informing subsequent cycles of inquiry.

Collaboration

Action research methods have evolved to include collaborative and negotiatory activities among various participants in the inquiry. Divisions between the roles of researchers and participants are frequently permeable; researchers are often defined as both full participants and external experts who engage in ongoing consultation with participants. Criteria for collaboration include evident structures for sharing power and voice; opportunities to construct common language and understanding among partners; an explicit code of ethics and principles; agreement regarding shared ownership of data; provisions for sustainable community involvement and action; and consideration of generative methods to assess the process's effectiveness.

The collaborative partnerships characteristic of action research serves several purposes. The first is to integrate into the research several tenets of evidence-based responsibility rather than documentation-based accountability. Research undertaken for purposes of accountability and institutional justification often enforces an external locus of control. Conversely, responsibility-based research is characterized by job-embedded, sustained opportunities for participants' involvement in change; an emphasis on the demonstration of professional learning; and frequent, authentic recognition of practitioner growth.

Role of the Researcher

Action researchers may adopt a variety of roles to guide the extent and nature of their relationships with participants. In a *complete participant* role, the identity of the researcher is neither concealed nor disguised. The researchers' and participants' goals are synonymous; the importance of participants' voice heightens the necessity that issues of anonymity and confidentiality are the subject of ongoing negotiation. The *participant observer* role encourages the action researcher to negotiate levels of accessibility and membership in the participant group, a process that can limit interpretation of events and perceptions. However, results derived from this type of involvement may be granted a greater degree of authenticity if participants are provided the opportunity to review and revise perceptions through a member check of observations and anecdotal data. A third possible role in action research is the *observer participant*, in which the researcher does not attempt to experience the activities and events under observation

but negotiates permission to make thorough and detailed notes in a fairly detached manner. A fourth role, less common to action research, is that of the *complete observer*, in which the researcher adopts passive involvement in activities or events, and a deliberate—often physical—barrier is placed between the researcher and the participant in order to minimize contamination. These categories only hint at the complexity of roles in action research. The learning by the participants and by the researcher is rarely mutually exclusive; moreover, in practice, action researchers are most often full participants.

Intertwined purpose and the permeability of roles between the researcher and the participant are frequently elements of action research studies with agendas of emancipation and social justice. Although this process is typically one in which the external researcher is expected and required to provide some degree of expertise or advice, participants—sometimes referred to as internal researchers—are encouraged to make sense of, and apply, a wide variety of professional learning that can be translated into ethical action. Studies such as these contribute to understanding the human condition, incorporate lived experience, give public voice to experience, and expand perspectives of participant and researcher alike.

A Case for and Against Action Research

Ontological and epistemological divisions between qualitative and quantitative approaches to research abound, particularly in debates about the credibility of action research studies. On one hand, quantitative

Figure 1 Lewin's Model of Action Research

Source: Lewin, K. (1946). Action research and minority problems. *Journal of Social Issues*, 2, 34–46.

research is criticized for drawing conclusions that are often pragmatically irrelevant; employing methods that are overly mechanistic, impersonal, and socially insensitive; compartmentalizing, and thereby minimizing, through hypothetico-deductive schemes, the complex, multidimensional nature of human experiences; encouraging research as an isolationist and detached activity void of, and impervious to, interdependence and collaboration; and forwarding claims of objectivity that are simply not fulfilled.

On the other hand, qualitative aspects of action research are seen as quintessentially unreliable forms of inquiry because the number of uncontrolled contextual variables offers little certainty of causation. Interpretive methodologies such as narration and autobiography can yield data that are unverifiable and potentially deceptive. Certain forms of researcher involvement have been noted for their potential to unduly influence data, while some critiques contend that Hawthorne or halo effects—rather than authentic social reality—are responsible for the findings of naturalist studies.

Increased participation in action research in the latter part of the 20th century paralleled a growing demand for more pragmatic research in all fields of social science. For some humanities practitioners, traditional research was becoming irrelevant, and their social concerns and challenges were not being adequately addressed in the findings of positivist studies. They found in action research a method that allowed them to move further into other research paradigms or to commit to research that was clearly bimethodological. Increased opportunities in social policy development meant that practitioners could play a more important role in conducting the type of research that would lead to clearer understanding of social science phenomena. Further sociopolitical impetus for increased use of action research derived from the politicizing effects of the accountability movement and from an increasing solidarity in humanities professions in response to growing public scrutiny.

The emergence of action research illustrates a shift in focus from the dominance of statistical tests of hypotheses within positivist paradigms toward empirical observations, case studies, and critical interpretive accounts. Research protocols of this type are supported by several contentions, including the following:

- The complexity of social interactions makes other research approaches problematic.
- Theories derived from positivist educational research have been generally inadequate in explaining social interactions and cultural phenomena.
- Increased public examination of public institutions such as schools, hospitals, and corporate organizations requires insights of a type that other forms of research have not provided.
- Action research can provide a bridge across the perceived gap in understanding between practitioners and theorists.

Reliability and Validity

The term *bias* is a historically unfriendly pejorative frequently directed at action research. As much as possible, the absence of bias constitutes conditions in which reliability and validity can increase. Most vulnerable to charges of bias are action research inquiries with a low saturation point (i.e., a small *N*), limited interrater reliability, and unclear data triangulation. Positivist studies make attempts to control external variables that may bias data; interpretivist studies contend that it is erroneous to assume that it is possible to do *any* research—particularly human science research—that is uncontaminated by personal and political sympathies and that bias can occur in the laboratory as well as in the classroom. While value-free inquiry may not exist in any research, the critical issue may not be one of credibility but, rather, one of recognizing divergent ways of answering questions associated with purpose and intent. Action research can meet determinants of reliability and validity if primary contextual variables remain consistent and if researchers are as disciplined as possible in gathering, analyzing, and interpreting the evidence of their study; in using triangulation strategies; and in the purposeful use of participation validation. Ultimately, action researchers must reflect rigorously and consistently on the places and ways that values insert themselves into studies and on how researcher tensions and contradictions can be consistently and systematically examined.

Generalizability

Is any claim of replication possible in studies involving human researchers and participants? Perhaps even more relevant to the premises and intentions that underlie action research is the question, Is this *desirable* in contributing to our understanding of the social world? Most action researchers are less concerned with the traditional goal of generalizability than with capturing the richness of unique human experience and meaning. Capturing this richness is often accomplished by reframing determinants of generalization and

avoiding randomly selected examples of human experience as the basis for conclusions or extrapolations. Each instance of social interaction, if thickly described, represents a slice of the social world in the classroom, the corporate office, the medical clinic, or the community center. A certain level of generalizability of action research results may be possible in the following circumstances:

- Participants in the research recognize and confirm the accuracy of their contributions.
- Triangulation of data collection has been thoroughly attended to.
- Interrater techniques are employed prior to drawing research conclusions.
- Observation is as persistent, consistent, and longitudinal as possible.
- Dependability, as measured by an auditor, substitutes for the notion of reliability.
- Confirmability replaces the criterion of objectivity.

Ethical Considerations

One profound moral issue that action researchers, like other scientists, cannot evade is the use they make of knowledge that has been generated during inquiry. For this fundamental ethical reason, the premises of any study—but particularly those of action research—must be transparent. Moreover, they must attend to a wider range of questions regarding intent and purpose than simply those of validity and reliability. These questions might include considerations such as the following:

- Why was this topic chosen?
- How and by whom was the research funded?
- To what extent does the topic dictate or align with methodology?
- Are issues of access and ethics clear?
- From what foundations are the definitions of science and truth derived?
- How are issues of representation, validity, bias, and reliability discussed?
- What is the role of the research? In what ways does this align with the purpose of the study?
- In what ways will this study contribute to knowledge and understanding?

A defensible understanding of what constitutes knowledge and of the accuracy with which it is portrayed must be able to withstand reasonable scrutiny from different perspectives. Given the complexities of human nature, complete understanding is unlikely to

result from the use of a single research methodology. Ethical action researchers will make public the stance and lenses they choose for studying a particular event. With transparent intent, it is possible to honor the unique, but not inseparable, domains inhabited by social and natural, thereby accommodating appreciation for the value of multiple perspectives of the human experience.

Making Judgment on Action Research

Action research is a relatively new addition to the repertoire of scientific methodologies, but its application and impact are expanding. Increasingly sophisticated models of action research continue to evolve as researchers strive to more effectively capture and describe the complexity and diversity of social phenomena.

Perhaps as important as categorizing action research into methodological compartments is the necessity for the researcher to bring to the study full self-awareness and disclosure of the personal and political voices that will come to bear on results and action. The action researcher must reflect on and make transparent, prior to the study, the paradoxes and problematics that will guide the inquiry and, ultimately, must do everything that is fair and reasonable to ensure that action research meets requirements of rigorous scientific study. Once research purpose and researcher intent are explicit, several alternative criteria can be used to ensure that action research is sound research. These criteria include the following types, as noted by David Scott and Robin Usher:

Aparadigmatic criteria, which judge natural and social sciences by the same strategies of data collection and which apply the same determinants of reliability and validity

Diparadigmatic criteria, which judge social phenomena research in a manner that is dichotomous to natural science events and which apply determinants of reliability and validity that are exclusive to social science

Multiparadigmatic criteria, which judge research of the social world through a wide variety of strategies, each of which employs unique postmodern determinants of social science

Uniparadigmatic criteria, which judge the natural and social world in ways that are redefined and reconceptualized to align more appropriately with a growing quantity and complexity of knowledge

In the final analysis, action research is favored by its proponents because it

- honors the knowledge and skills of all participants
- allows participants to be the authors of their own incremental progress
- encourages participants to learn strategies of problem solving
- promotes a culture of collaboration
- enables change to occur in context
- enables change to occur in a timely manner
- is less hierarchical and emphasizes collaboration
- accounts for rather than controls phenomena

Action research is more than reflective practice. It is a complex process that may include either qualitative or quantitative methodologies, one that has researcher and participant learning at its center. Although, in practice, action research may not often result in high levels of critical analysis, it succeeds most frequently in providing participants with intellectual experiences that are illuminative rather than prescriptive and empowering rather than coercive.

ADAPTIVE DESIGNS IN CLINICAL TRIALS

Adaptive designs in clinical trials are derivations of randomized clinical trials that modify the randomization ratio during the study. In adjusting the randomization ratio during the study, adaptive designs in clinical trials maximize the likelihood of participants experiencing positive outcomes and minimize the likelihood of participants experiencing poor outcomes. Adaptive designs in clinical trials follow a three-step procedure. In Step 1, participants are randomly allocated to one of the interventions with the probability of allocation into each intervention being specified by the randomization ratio. In Step 2, participants' outcome and/or covariate data are collected. In Step 3, the randomization ratio is updated based on the collected outcome and/or covariate data. Steps 1 through 3 are then repeated until the desired number of participants has been randomized.

Randomization Ratios

A randomization ratio is the ratio of the probabilities of being randomly allocated to each of the intervention arms. A fixed randomization ratio is held constant throughout a study, but an adaptive randomization ratio can change during a study.

Data for Adjusting the Randomization Ratio

In adaptive designs in clinical trials, the randomization ratio is adjusted using outcome and/or covariate data. Outcome data refer to data reflecting the effectiveness of the intervention, typically collected at the end of the study. For example, a study intended to improve reading comprehension would likely use some measure of reading comprehension as the primary outcome, and data from this reading comprehension measure would be used to adjust the randomization ratio in an outcome-adaptive design.

Covariate data refer to information pertaining to the participants in the study (e.g., sex, race, age). Covariate-adaptive designs adjust the randomization ratio based on the covariate data with the goal of minimizing between-group differences. For example, a covariate-adaptive design might adjust the randomization ratio to produce similar male-to-female ratios in the intervention arms. While covariate data could solely be used to adjust the randomization ratio, a study using a fixed randomization ratio

would theoretically balance covariate data across intervention arms given a sufficiently large sample size. Thus, it appears most likely that studies using an adaptive design will use either outcome data to adjust the randomization ratio or a combination of outcome and covariate data to adjust the randomization ratio.

Assumptions

Adaptive designs in clinical trials make two assumptions. First, participant randomizations must be spread throughout the course of the study. Because adaptive designs in clinical trials use outcome and/or covariate data to adjust the randomization ratio for later randomizations, data must first be collected from some participants in order to benefit later randomizations of other participants. Second, the time between participant randomization and outcome data collection must be reasonably quick when using an outcome-adaptive design. When the randomization ratio is adjusted using outcome data, an extended period between participant randomization and outcome data collection would delay adjustment of the randomization ratio. This concern is less relevant for covariate-adaptive designs since covariate information can usually be collected quickly.

Families of Adaptive Designs

Since their inception, several families of statistical models have been used to define types of adaptive designs in clinical trials. There are the play-the-winner models, drop-the-loser models, biased coin designs, bandit models, random N models, and target R^* . While an in-depth discussion of these models is beyond the scope of this entry, each of these models defines rules for adjusting the randomization ratio.

Generally, these statistical models for adaptive designs in clinical trials were created as alternatives to randomized clinical trials using fixed randomization ratios. However, the early models within each family were typically deterministic, with each participant's allocation being completely determined by the previous participant's allocation and outcome. For example, early play-the-winner models would allocate the second participant based on the outcome and/or covariate data of the first participant, the third participant based on the outcome and/or covariate data of the second participant, and so on. Notably, this is *not* random assignment, since it would be known how the next participant was to be allocated. However, later work extended these models to probabilistic

allocation, whereby the previous participant's outcome and/or covariate data affected the randomization ratio for the next participant but did not determine allocation.

Advantages

Adaptive designs in clinical trials use outcome and/or covariate data to adjust the randomization ratio. Because the randomization ratio reflects the data from previous participants, the randomization ratio maximizes the likelihood of participants experiencing a positive outcome and minimizes the likelihood of participants experiencing a negative outcome. In some fields (e.g., cancer research), maximizing potential benefit and minimizing potential risk are of the utmost importance.

Limitations

Two limitations of adaptive designs in clinical trials are reduced statistical power and threats to internal validity.

Reduced Statistical Power

Because participant randomizations are correlated with the outcomes and/or covariates, adaptive designs in clinical trials have reduced statistical power compared to randomized clinical trials using fixed randomization ratios. Consequently, adaptive designs in clinical trials will require more participants to achieve the same level of statistical precision.

Threats to Internal Validity

Because adaptive designs in clinical trials spread randomizations across the duration of the study, threats to internal validity (e.g., history effect, maturation) may differentially affect participants. For example, a study that is completed over the course of an academic year may have reduced internal validity because of developmental changes that cause students randomized at the beginning of the study to be qualitatively different from students randomized at the end of the study.

ADVERSE EVENT REPORTING

Adverse event reporting entails documenting and reporting harmful outcomes observed during research to a designated monitoring committee or system, review board, and/or institution. Adverse events are unanticipated problems experienced during research which places human subjects or others at a greater risk of harm than was previously known, including physical, psychological, economic, or social harm. Such events may lead to a pause and/or termination of the research to fully evaluate the direct or indirect cause of the harmful events. These can be thought of primarily as harmful events or outcomes not expected by researchers, and not included in Institutional Review Board (IRB) or other review submissions. In addition, expected adverse events, if more severe than previously known, are also reported and further evaluated. Thus, unexpected harmful events, or expected adverse events exceeding harm thresholds previously known, are reportable events to the monitoring committee or system, review board, and/or institution under which the research is supported. Research (e.g., biomedical, social, psychological) under the realm of federal, state, or institutional support dealing with human subjects include adverse effect reporting. Using a few examples, this entry further explores unexpected and adverse events and the reporting of such events.

Examples

The following are examples requiring adverse event reporting:

1. A randomized clinical trial (RCT) is assessing a new antiretroviral drug for HIV/AIDS patients. The lead researcher, Jane Hitti, discovered that during the testing period, severe liver damage occurred in several research subjects in the intervention arm receiving the drug.
2. Conor Duggan and other researchers reported on a 2014 intervention study for adults with personality disorders. Investigators noticed an increase in negative mental health events (e.g., self-harm, overdoses) beyond what is normally seen in this population
3. A vaccine to protect individuals from a new virus results in what appears to be an increase in severe allergic reactions after receiving the vaccine injection, including anaphylaxis. This happened as part of a 2003 Centers for Disease Control and Prevention study as reported by Weigong Zhou and colleagues.

In the first example, the study was shut down due to greater than expected liver toxicity. In the second example, the adverse events were reported to the public funding agency's data monitoring committee—the study was not stopped, but no new research participants were recruited. In the third example, the anaphylaxis was reported to the Vaccine Adverse Event Reporting System for further evaluation and analysis; it was subsequently deemed a rare event allowing for continued vaccinations.

Unexpected and Expected Adverse Events

The most familiar adverse event reporting—what individuals read in scientific journals, or read, see, and hear on mass and social media platforms—concerns unexpected adverse events in RCTs, where research subjects are randomly assigned to a control group or an intervention group, then followed over time to evaluate change due to the intervention. Hypotheses regarding positive outcomes are offered by researchers, and any expected negative consequences are discussed, including safety measures to address adverse events. These issues are covered as part of the IRB submission for human subjects, normally submitted through a participating institution or similar entity. In the United States, to receive federal, state, or institution funding and adhere to Department of Health and Human Services

(DHHS) and Food and Drug Administration (FDA) guidelines, IRB approval is required—thus, researchers working with human subjects must also have access to an IRB and associated oversight.

Unexpected adverse events entail harmful outcomes to human subjects or others not expected. Such issues were not anticipated by researchers, nor documented in IRB or review submissions, nor were human subjects made aware of the possible negative outcomes. These events are then reported to the requisite monitoring committee or institution for further review. In some instances, the ongoing research is halted while review of such events are investigated. For example, in 2006, Edward Mills and colleagues documented a number of RCTs regarding treatments for HIV/AIDS (mostly anti-retroviral treatments) that were stopped due to unexpected adverse events, including extreme treatment toxicity, side effects, encephalopathy, and death.

Expected adverse events are those events expected to occur during the research but are not more severe or prevalent than what was previously known. Such events are documented and addressed by researchers but do not fall directly under adverse event reporting unless they exceed what was expected. For example, an expected adverse event for medical researchers testing a new treatment for acne might include subjects experiencing dry lips and skin. Safety measures and protocols are covered in the review submission to address such physiological reactions. In another example, a psychologist might utilize personal interviews to evaluate one-night sexual encounters, yet also be aware that the interviews might “trigger” suppressed memories of sexual distress in a few of those interviewed—again, safety protocols are established for those possible cases. Essentially, if expected adverse events occur in research, then protocols are in place to address the events.

However, when expected adverse events are more prevalent and/or severe than previously known, then adverse event reporting is warranted. Using the previous examples, if medical researchers investigating an acne medication notice severe lip cracking and skin peeling (thus, not just dry lips and skin), or if the psychologist notices interview participants experiencing severe sexual distress requiring immediate counseling, then such adverse events are reportable. Research can be temporarily halted or shut down if such events exceed what was expected. For example, the study noted earlier by J. Hitti and colleagues (2004) was stopped, with the authors noting, “We observed greater than expected toxicity associated with nevirapine during the first phase of this randomized trial” (p. 774). The 1989 Cardiac Arrhythmia Suppression Trial, which

focused on antiarrhythmic therapy, was selectively stopped due to increases in mortality for some of the treatment arms of the study. Both these applied examples underscore that adverse events were expected, but exceeded what was anticipated, putting human subjects at greater risk. Jesse A. Berlin and colleagues (2008) outlined some general probabilities for adverse events above what is expected at background levels.

Other Issues With Adverse Event Reporting

Non-RCT Research Designs

As noted earlier, the familiar examples regarding adverse event reporting entail RCTs. However, any prospective research design involving an intervention (e.g., vaccine, therapeutic, behavior-change regimen) can yield adverse events with human subjects. For example, trials that are one-shot case study designs (one intervention group, no follow-up) can have adverse events; without a control group, resulting adverse events can be compared to background event reporting, and if unique or adverse events exceed background levels, then such events are reported. Laboratory-based observational research such as those conducted in the social and behavioral sciences can also cause adverse events. A classic example is the Stanford Prison Study, conducted by Philip Zimbardo in the early 1970s, where even the principal investigator succumbed to the “power of the situation” in his role as prison superintendent and influenced possible adverse events experienced by study participants. The study ended early due to these events and the principal investigator requested an ethics investigation. Even field-based participant-observational research studies can cause adverse events to those being observed, as the observers’ presence may negatively impact the population being evaluated.

Rare Event Occurrence

Adverse events can also be extremely rare events, but the detection or reporting may be delayed due to infrequency of observation. For example, Esther W. Chan and colleagues documented such negative events, noting serious adverse events such as death due to suicide for attention-deficit hyperactivity disorder treatments, and retinal detachment associated with the use of oral fluoroquinolones. Although not clearly detected in the original studies of these treatments, over time and with broader medication use, such events were subsequently documented and reported, calling the treatments into question.

Animal Subjects

Currently, adverse event reporting is not an absolute requirement with nonhuman subjects, although recommendations have been made (see Ferdowsian et al., 2020).

Where to Report Adverse Events

Different research protocols, IRBs, and funding institutions will require different reporting options. Also, the type of research conducted will determine where to report. In the United States, a few of the systems designed to monitor and capture adverse events include the Vaccine Adverse Event Reporting System, the Monitoring System for Adverse Events Following Immunization, and the FDA Adverse Event Reporting System designed as a database for postmarketing safety surveillance of drug and therapeutic biologic products. In addition, independent Data Safety and Monitoring Boards are often established for clinical trials.

AKAIKE INFORMATION CRITERION

The Akaike Information Criterion (AIC) is one of the first and among the most widely used model selection criteria. In general, a model selection criterion is a measure that summarizes how effectively a statistical model balances the competing objectives of parsimony and fidelity to the data used in its construction. AIC can be used to rank order a defined collection of candidate models and to identify a “best” model from among these candidates.

AIC was first introduced by Hirotugu Akaike in 1973 as an extension to the maximum likelihood principle, which assumes that the size and structure of a statistical model are known and that the data need only be used to estimate the associated (unknown) model parameters. Akaike described AIC as being based on an extension to this principle since the application of the criterion employs data for both the determination of the size and structure of the model and the estimation of its associated parameters. This entry provides a formal definition of AIC, contrasts the selection criterion and hypothesis-testing approaches for model selection,

gives practical notes for the use of AIC, and demonstrates the utility of AIC in an application based on epidemiological data.

Formal Definition

AIC serves as an asymptotically unbiased estimator of the expected Kullback–Leibler (KL) discrepancy between the model that gave rise to the data (i.e., the true or generating model) and a fitted candidate model. The KL discrepancy measures the degree of separation between two statistical models. Thus, for a sufficiently large sample, the fitted candidate model corresponding to the minimum value of AIC is ideally “closest” to the truth among the set of models under consideration.

To formally define AIC, consider a candidate collection of models $M_1, M_2, \dots, M_L$, each with corresponding parameter vector θ_k ($k = 1, \dots, L$). The dimension, or size, of each model describes the number of functionally independent parameters in θ_k and is denoted by d_k . We let $\hat{\theta}_k$ denote the estimator of θ_k obtained through maximizing the likelihood, $L(\theta_k | y)$, based on the data y . We define the AIC for model M_k as

$$\text{AIC}_k = -2\log L(\hat{\theta}_k | y) + 2d_k,$$

where the first term, $-2\log L(\hat{\theta}_k | y)$, captures the goodness of fit of the model, and the second term, called the penalty term, reflects model complexity. The goodness-of-fit term decreases in value with improved fidelity of the fitted model to the data at hand. The penalty term, $2d_k$, characterizes model complexity through the model’s dimension and therefore increases in value for models of larger size. Larger models are often associated with improved goodness of fit and hence smaller values for the corresponding term. However, the improvement in fit may be offset by increasingly large penalizations corresponding to greater model complexity. Conversely, smaller models are penalized less heavily for complexity but may be too simplistic to adequately accommodate the data at hand, yielding larger goodness-of-fit values. Among the candidate collection of models under consideration, the trade-off between goodness of fit and parsimony is then best optimized by the fitted model corresponding to the minimum AIC.

We may interpret AIC from a predictive standpoint by assuming interest in the prediction of a new panel of data, z , that is generated independently, but identically, to the fitting data, y . In this scenario, the prediction error of a model parameterized by θ_k can

be measured by $-2\log L(\hat{\theta}_k(y) | z)$, where we use the notation $\hat{\theta}_k(y)$ to denote the vector of parameter estimators obtained through the fitting data y . The mean error of prediction based on averaging this quantity over the joint distribution of y and z is equivalent to the expected KL discrepancy that underlies AIC. This suggests that in using AIC to select a model, assuming the prediction of data generated independently from, but identically to, the fitting data, one is attempting to choose the model that minimizes a measure of mean prediction error. This predictive interpretation relates to the optimality property of asymptotic efficiency. In large sample settings, an asymptotically efficient selection criterion will select the fitted candidate model that yields predictors that minimize the mean squared error of prediction. In 1981, Ritei Shibata proved this property held for AIC and other selection criteria.

Underlying Assumptions

The development of AIC relies on the asymptotic, or large-sample, properties of the maximum likelihood estimator. Akaike showed that $-2\log L(\hat{\theta}_k | y)$ serves as an optimistically biased estimator of the KL discrepancy. The bias is optimistic in the sense that $-2\log L(\hat{\theta}_k | y)$ underestimates the actual discrepancy, or disparity, between the fitted candidate model and the true model. Akaike showed that this bias may be corrected asymptotically through the adjustment, $2d_k$, thus giving rise to the definition of AIC previously provided. In small-sample settings, where the sample size n is small relative to the model dimension (e.g., $d_k \gtrsim n/2$), this asymptotic bias adjustment is no longer valid. As a result, in such small-sample applications, AIC does not properly penalize model complexity and often leads to the selection of unnecessarily large and complex models that poorly optimize between goodness of fit and parsimony. Recognizing this limitation, Nariaki Sugiura proposed a “corrected” AIC in 1978 that serves as an exactly unbiased estimator of the KL discrepancy provided that the candidate collection of models consists of normal linear regression models. This criterion, AICc, was later generalized for application in the frameworks of normal nonlinear regression models and time series autoregressive models, autoregressive moving average models, vector autoregressive models, normal multivariate linear regression models, and certain generalized linear models (GLMs) and linear mixed models, thereby

increasing its popularity as a small-sample alternative to AIC.

In addition to the large-sample requirement, AIC is developed under the assumption that the true model is subsumed by the candidate model. The practical implication of this assumption is that a fitted candidate model is assumed to be either correctly or overspecified. A correctly specified candidate model is one that appropriately represents the true model, whereas a model that is overspecified includes all of the requisite structure of the true model along with additional features extraneous to the true model. Kei Takeuchi introduced the Takeuchi Information Criterion in 1976 as an alternative to AIC that relaxes this strong assumption. While the goodness-of-fit terms of Takeuchi Information Criterion and AIC are identical, the criteria differ in their penalty terms. In contrast to AIC, Takeuchi Information Criterion penalizes models through a complex function of the sample data. This data-dependent penalization may be substantially less biased in its ability to correct for the optimism inherent in using the empirical log-likelihood to estimate the expected KL discrepancy. However, since this penalization is determined from the data, it could be much more variable than the data-independent penalization, $2d_k$, of AIC.

Contrast With Hypothesis Testing

Prior to the advent of AIC, model selection was largely restricted to the hypothesis-testing paradigm. In this framework, pairwise comparisons among nested models are performed. Under the null hypothesis, the smaller, nested model is assumed to represent the truth. This model is rejected in favor of the larger candidate model if the data depart substantially from what would be expected if the smaller model were indeed true. To gauge the observed degree of departure, or evidence, against the null-hypothesized model, a p value is computed and compared to an arbitrarily defined threshold of statistical significance, with the most popular being the .05 threshold first suggested by Ronald Fisher in the early 20th century. Akaike's introduction of AIC offered an alternative to this framework and subsequently initiated the development of a growing collection of model selection criteria. In contrast to the hypothesis-testing framework, the use of model selection criteria does not constitute an attempt to determine which of two competing nested models represents the unknown truth but rather to assess candidate models on the basis of how effectively

various models approximate the truth. Given a collection of candidate models, nested or otherwise, selection criteria allow one to determine those models that conform well to the data at hand (goodness of fit) without an unnecessary degree of structural complexity (parsimony). A favored model should also be generalizable in the sense that it should adequately describe or predict new data generated under the true model.

Practical Notes

In addition to the comparison of nonnested models, AIC can be used for the comparison of models based on different probability distributions. As an example, AIC may be used to decide between a GLM that employs a Poisson distribution for a count response and a GLM that utilizes a negative binomial distribution to account for overdispersion. If such comparisons are made, all terms in each empirical likelihood must be retained in the computation of AIC. This practice is in contrast to comparisons between models based on the same distribution, where data-independent terms may be discarded. AIC may not be used to compare models based on different transformations of the response variable.

While it is generally advised to pick the candidate model with the minimum value of AIC, there may be other, equally compelling candidate models indicated by the data. Table 1 provides guidelines that are commonly used to assess the level of empirical support for a given model based on the difference between the model's AIC value and the minimum AIC value in the candidate collection.

Table 1 Recommended Selection Guidelines Based on AIC Differences

$AIC_i - AIC_{min}$	<i>Level of Empirical Support for Model i</i>
0–2	Substantial
4–7	Considerably less
>10	Essentially none

Application

To illustrate the utility of AIC, we consider modeling data on the yearly incidence (i.e., number of new cases) of AIDS in Belgium from the outset of the epidemic in 1981 to the year 1993. Figure 1 depicts a nonlinear trend in AIDS incidence that peaks in 1991 and is followed by a steady decline in new AIDS cases over subsequent years.

To properly model this nonlinear trend over time, we consider various polynomial models within the

generalized linear modeling framework. Specifically, we assume that our response follows a Poisson distribution, and we specify a log-link function to relate the mean incidence to polynomials based on the yearly time index. Four polynomial models are entertained, each of increasing degree, d . We consider a linear ($d = 1$) model, quadratic ($d = 2$) model, cubic model ($d = 3$), and a model containing polynomial terms up to degree 12. Figure 2 depicts the fits of each polynomial to the data displayed in Figure 1.

Figure 1 AIDS Incidence in Belgium, 1981–1993

Figure 2 GLM Polynomial Fits to AIDS Incidence in Belgium, 1981–1993

The upper left plot depicting the linear model fit ($d = 1$) only roughly approximates the trend in incidence and fails to capture the change in trend after 1991. This suggests a substantial degree of bias in the prediction of AIDS incidence over the range of years that are under consideration. The quadratic and cubic models, which are more complex than the linear model, better capture the nonlinearity in incidence over time and therefore exhibit reduced bias relative to the linear model. The most complex model ($d = 12$) yields a fitted curve that passes through each data point and is therefore not susceptible to bias problems. However, this model is beset by a high amount of variability in that the fitted curve fluctuates dramatically about the data, especially for the years 1991–1993. The fits of these models demonstrate the bias–variability trade-off, which relates directly to the optimization of goodness of fit and parsimony that serves as the impetus for the development of model selection criteria. Simpler, more parsimonious models are those with a larger amount of bias and a more minimal degree of variability. This is apparent in the simplest, linear model that depicts a smooth (low variability) fitted curve that tends to be either too low or too high to adequately characterize the true incidence values (high bias). In contrast, the most complex model ($d = 12$) yields a fitted curve that passes through every data point (low bias) but is extremely “wiggly” (high variability). The polynomial degree, model dimension, value of $-2\log L(\hat{\theta}_k | y)$ and AIC value for each of the four models are provided in Table 2.

The model with the minimum AIC is the quadratic model, and thus, within the collection of models under consideration, this model provides the best balance between goodness of fit and parsimony. However, one may notice that the cubic model has an AIC value that is only slightly larger than the quadratic model. Looking to the selection guidelines provided in Table 1, we would observe that the difference between the cubic and quadratic AIC values is 1.8, suggesting empirical support for both the quadratic and cubic models. Looking to Figure 2, however, we see that the fits of the quadratic and cubic models are virtually identical.

Table 2 AIC Values and Other Relevant Modeling Quantities

Polynomial Degree (d)	Model Dimension (d_k)	$-2\log L(\hat{\theta}_k y)$	AIC
1	2	162.4	166.4
2	3	90.9	96.9
3	4	90.7	98.7
12	13	81.7	107.7

Indeed, the addition of the cubic term results in only a slight decrease in the goodness-of-fit term, meaning that the difference in AIC values is close to the difference in penalizations (of two units). Thus, one may convincingly argue in favor of the quadratic model by virtue of Occam’s Razor, the philosophical principle best described by the statement, “Everything should be made as simple as possible, but not simpler.”

ALTERNATING TREATMENTS DESIGN

Alternating treatment designs, also called multielement designs, are single-case experimental designs, characterized by a rapid and frequent alternation of conditions. The specific sequence of conditions is usually determined at random, which enhances internal validity. This design feature makes possible the use of randomization tests, which improves statistical conclusion validity. Furthermore, replication of different alternation sequences across participants in the context of the same study is possible. In this entry, the main features of alternating treatment designs are described, distinguishing different ways of determining the alternation sequence and different uses. Indications for data analysis are also provided.

Main Features

Types of Designs and Applicability

The rapid alternation of conditions that takes place in an alternating treatments design distinguishes it from single-case phase designs (e.g., multiple baseline designs and withdrawal or reversal designs), which are characterized by more consecutive measurements for the same condition. It is necessary to distinguish different situations that can be described as an “alternating treatments design.”

Alternating treatment designs with restricted randomization or block randomization

Although it is possible to determine the sequence of conditions through counterbalancing, it is more common to use randomization. Two different ways of determining the alternating sequence at random need to be mentioned.

On one hand, the random alternation scheme can impose that no condition is repeated until all have been conducted. Another way of describing the same procedure is to establish blocks of the same size as the number of conditions being compared and to determine at random the order of the conditions within each block. This design is called a randomized block design (although this name could induce confusion with a group design of the same name) or an alternating treatments design with block randomization. Other terms have also been used in the literature to describe this design, for instance, “alternating treatments design with a blocked pairs random assignment procedure” or “alternating treatments design in which the order of conditions is block randomized.” The randomly determined sequence using block randomization is equivalent to the *N*-of-1 trials used in the health sciences, where the several random-order blocks are called multiple crossovers.

On the other hand, the random alternation scheme can impose a limit on the consecutive administrations of the same condition. It is very common to require a maximum of two consecutive sessions per condition. Such a design is called a restricted alternating treatment design or an alternating treatments design with restricted randomization or with a semi-random order of conditions.

Alternating treatment designs with restricted randomization and with block randomization are applicable to reversible behaviors and to interventions that can be introduced and removed fast, without leaving lasting effects. Moreover, unlike ABAB and multiple baseline designs, alternating treatment designs can be used to address questions about the relative strength

of two interventions, rather than only studying efficacy in comparison to a control condition. It is possible and common to alternate more than two conditions.

For both kinds of alternating treatment designs, the rapid alternation of conditions is said to take place in a “comparison phase,” which may be the only phase of the alternating treatment designs. However, it is also possible (although not compulsory) to have an initial baseline phase and a final phase in which only the most effective condition is used.

Adapted alternating treatment designs

Adapted alternating treatment designs are those in which at least two independent behaviors or outcome variables are treated. These behaviors are non-reversible, and the main aim is to explore which of two effective interventions is more efficient (i.e., enables faster learning). In an adapted alternating treatment design, it is critical to have the same number of sessions per condition and the researchers typically follow a procedure equivalent to block randomization.

Addressing Threats to Validity

In an alternating treatments design, several threats to internal validity are addressed. First, in relation to history, given that there are several alternations of the condition, it is less likely that external events occur simultaneously with the change in conditions. Second, there are several effects related to potential interactions among conditions and different strategies to deal with them. In relation to order effects (also called sequence effects), the random determination of the order of the conditions reduces this possibility, as there are many possible orders (e.g., AB, AC, BA, BC, CA, and CB when comparing three conditions). In relation to carryover effects, the control condition can be alternated with the intervention conditions in the comparison phase, in order to explore whether there are any systematic changes even in the absence of an active intervention. Fourth, to reduce the possibility of multiple treatment interference (i.e., the possibility that the effect of an intervention applied in frequent alternation with another intervention is different from presenting the intervention alone), the researchers can increase the amount of time between sessions (including washout periods). Finally, in terms of quantity, five repetitions of the alternation are required for meeting current design standards for solid evidence. Similarly, at least five measurements per condition are recommended. The demonstration of experimental control is boosted by

replication across several participants, each with their own randomly determined sequence.

Data Analysis

This section discusses options for analyzing the data from alternating treatment designs.

The Importance of the Design for the Data Analysis

The use of randomization in the design enables applying a randomization test for data analytical purposes. A randomization test can provide a p value for observed difference between conditions, representing the probability of obtaining such a larger difference or a larger one only due to chance (i.e., enabling a tentative inference about causality, rather than an inference about a population of individuals or measurements).

The statistical power of the randomization test is related to the number of possible alternation sequences, and the number of sequences that can be obtained for an alternating treatment design with block randomization is less than for an alternating treatment design with restricted randomization. For instance, a sequence such as AABBAABBAABB is possible only for an alternating treatment design with restricted randomization. In contrast, the visual and certain quantitative comparisons between conditions (mentioned next in the entry) are more straightforward for an alternating treatments design with block randomization, as the logical comparison is performed within blocks. In contrast, a sequence such as AABBAABBAABB could be divided in different segments for comparing adjacent conditions (e.g., AABBAABBAABB, AAB-BA-AB-BA-ABB or AAB-BAA-BBA-ABB). Furthermore, some alternating treatments design with restricted randomization may entail unequal number of measurement occasions per condition, which may also be limiting for certain data analytical procedures.

Finally, for an adapted alternating treatments design, the data analytical approach can be different, as the emphasis is put on the speed at which a certain level is reached. Thus, it is common to establish a mastery criterion specifying when the acquisition of the target behaviors takes place prior to gathering the data and to assess for which of the conditions this criterion is reached faster. It is also common for the graphical representations to include data points for both conditions for the same measurement occasion (i.e., for the same value in the abscissa). This makes visual analysis more straightforward. The following text deals with data analytical procedures for

alternating treatments design with restricted randomization or with block randomization.

Visual Inspection

Visual inspection is suggested as a first choice for analyzing the degree to which the data path for one condition are different from (and superior to) the data path of the other condition. The data paths are represented by lines connecting the measurements belonging to the same condition. Thus, visual analysts assess the magnitude and consistency of the separation or differentiation between these connecting lines (e.g., whether they cross or not and what is the vertical distance between them).

Quantifying Differentiation

For quantifying differentiation, a specific version of the percentage of nonoverlapping data has been proposed: the first measurement for Condition A is compared with the first measurement for Condition B, the second measurement for Condition A is compared with the second measurement for Condition B, and so forth. This technique quantifies the percentage of comparisons for which there is superiority of one condition over another. The main limitations of this approach are that (a) the measurements compared may not be adjacent and could be separated by several other data points (e.g., for the second measurement for each condition in a sequence such as AABABBAABB) and (b) some of the measurements may not be used if there is an unequal number of measurements per condition. The “visual structured criterion” assesses whether the number of comparisons for which one condition is superior can be considered to represent more than chance superiority. The assessment is performed comparing the superiority observed to the cutoff points that the researchers derived empirically.

In contrast to the percentage of nonoverlapping data and the visual structured criterion, which quantify superiority in ordinal terms, the comparison involving actual and linearly interpolated values (ALIV) assesses the magnitude of effect by focusing on the average amount of distance between the data paths. What is meant by “linearly interpolated values” are the Condition A points located on the data paths (i.e., the connecting lines) for the measurement occasions for which Condition B actually takes place and, analogously, Condition B points located on the data paths (i.e., the connecting lines) for the measurement occasions for which Condition A actually takes place.

By focusing on the comparison of data paths, the visual structured criterion and ALIV aim to mimic the

data analytical approach of visual analysts and to provide quantifications that would summarize the outcome of the assessment. Only ALIV quantifies the magnitude of superiority of one condition over the other.

Tentative Causal Inference

Beyond the comparison of data paths, randomization tests are the first statistical options proposed for alternating treatments designs. Randomization tests provide information about statistical significance, without relying on assumptions of random sampling or regarding the shape of the distribution of the data. The likelihood of the outcome obtained under the null hypothesis of no difference between conditions is rather based on a reference distribution based on all possible alternation sequences under the randomization scheme used. The use of randomization tests is thus justified by the random determination of the alternating sequence. The test statistic usually suggested is the mean difference, which is logical due to its frequent use as a summary measure in alternating treatments design. This analytical option, as well as the possibility to select an alternating sequence at random for design of the study, is implemented in the ShinySCDA website. However, the mean difference does not represent the comparison between data paths as well as ALIV does. A randomization test for ALIV has been shown to have adequate statistical properties. Data analysis via ALIV, alongside a graphical representation of the data, can be obtained using another website: Data Analysis Techniques for Alternating Treatments Designs.

Additional Analytical Options

Additional data analytic alternatives include piecewise or multilevel regression and local regression with nonparametric smoothers. It is not clear whether applied researchers would be able to easily use and correctly interpret the results of these latter analytical options, which is why this entry emphasizes the comparison of data paths and the use of a statistical test that is not based on large sample approximations.

ALTERNATIVE HYPOTHESES

The alternative hypothesis is the hypothesis that is inferred, given a rejected *null hypothesis*. Also called the *research hypothesis*, it is best described as an explanation for why the null hypothesis was rejected. Unlike the null, the alternative hypothesis is usually of most interest to the researcher.

This entry distinguishes between two types of alternatives: the *substantive* and the *statistical*. In addition, this entry provides an example and discusses the importance of experimental controls in the inference of alternative hypotheses and the rejection of the null hypothesis.

Substantive or Conceptual Alternative

It is important to distinguish between the substantive (or conceptual, scientific) alternative and the statistical alternative. The conceptual alternative is that which is inferred by the scientist given a rejected null. It is an explanation or theory that attempts to account for why the null was rejected. The statistical alternative, on the other hand, is simply a logical complement to the null that provides no substantive or scientific explanation as to why the null was rejected. When the null hypothesis is rejected, the statistical alternative is inferred in line with the Neyman–Pearson approach to hypothesis testing. At this point, the substantive alternative put forth by the researcher usually serves as the “reason” that the null was rejected. However, a rejected null does not by itself imply that the researcher’s substantive alternative hypothesis is correct. Theoretically, there could be an infinite number of explanations for why a null is rejected.

Example

An example can help elucidate the role of alternative hypotheses. Consider a researcher who is comparing the effects of two drugs for treating a disease. The researcher hypothesizes that one of the two drugs will be far superior in treating the disease. If the researcher rejects the null hypothesis, he or she is likely to infer that one treatment performs better than the other. In this example, the statistical alternative is a statement about the population parameters of interest (e.g., population means). When it is inferred, the conclusion is that the two means are not equal, or equivalently, that the samples were drawn from distinct populations. The researcher must then make a substantive “leap” to infer that one treatment is superior to the other. There may be many other possible explanations for the two means’ not being equal; however, it is likely that the researcher will infer an alternative that is in accordance with the original purpose of the scientific study (such as wanting to show that one drug outperforms the other). It is important to remember, however, that concluding that the means are not equal (i.e., inferring the statistical alternative hypothesis) does not provide any scientific evidence at all for the chosen conceptual alternative. Particularly when it is not

possible to control for all possible extraneous variables, inference of the conceptual alternative hypothesis may involve a considerable amount of guesswork, or at minimum, be heavily biased toward the interests of the researcher.

A classic example in which an incorrect alternative can be inferred is the case of the disease malaria. For many years, it was believed that the disease was caused by breathing swamp air or living around swamplands. In this case, scientists comparing samples from two populations (those who live in swamplands and those who do not) could have easily rejected the null hypothesis, which would be that the rates of malaria in the two populations were equal. They then would have inferred the statistical alternative, that the rates of malaria in the swampland population were higher. Researchers could then infer a conceptual alternative—*swamplands cause malaria*. However, without experimental control built into their study, the conceptual alternative is at best nothing more than a convenient alternative advanced by the researchers. As further work showed, mosquitoes, which live in swampy areas, were the primary transmitters of the disease, making the swamplands alternative incorrect.

The Importance of Experimental Control

One of the most significant challenges posed by an inference of the scientific alternative hypothesis is the infinite number of plausible explanations for the rejection of the null. There is no formal statistical procedure for arriving at the correct scientific alternative hypothesis. Researchers must rely on experimental control to help narrow the number of plausible explanations that could account for the rejection of the null hypothesis. In theory, if every conceivable extraneous variable were controlled for, then inferring the scientific alternative hypothesis would not be such a difficult task. However, since there is no way to control for every possible confounding variable (at least not in most social sciences, and even many physical sciences), the goal of good researchers must be to control for as many extraneous factors as possible. The quality and extent of experimental control is proportional to the likelihood of inferring correct scientific alternative hypotheses. Alternative hypotheses that are inferred without the prerequisite of such things as control groups built into the design of the study or experiment are at best plausible explanations as to why the null was rejected, and at worst, fashionable hypotheses that the researcher seeks to endorse without the appropriate scientific license to do so.

Concluding Comments

Hypothesis testing is an integral part of every social science researcher's job. The statistical and conceptual alternatives are two distinct forms of the alternative hypothesis. Researchers are most often interested in the conceptual alternative hypothesis. The conceptual alternative hypothesis plays an important role; without it, no conclusions could be drawn from research (other than rejecting a null). Despite its importance, hypothesis testing in the social sciences (especially the softer social sciences) has been dominated by the desire to reject null hypotheses, whereas less attention has been focused on establishing that the correct conceptual alternative has been inferred. Surely, anyone can reject a null, but few can identify and infer a correct alternative.

ALTERS

Alters are most aptly defined as the social actors, part of one's socially constructed network, without which one's membership in, and connection to, the broader

societies in which one finds himself or herself embedded would be affected. The formal study of alters within social networks, via social network analysis, first appeared within the scholarly literature (beginning in the field of sociology) in the 1930s and has since become a salient area of empirical interest within the fields of communication, psychology, anthropology, and business administration. Much research has been devoted, for example, to better understanding how certain alters provide ego (oneself) with increased opportunities for dependent variables such as information, decision-making influence, and access to job opportunities. That is, as a result of producing social network ties with alters who can provide ego with certain outcomes, these network alters become more important within ego's network as compared to others. This has salient implications for the production of social capital, best defined as the benefits linked to the accumulation of network ties to alters who can, at some point and in some way, shape, form, or provide ego with something of import.

Research indicates that such outcomes of social capital (being connected to alters who can ultimately provide fruitful rewards) can range from being the first to know about intraorganizational gossip to having access to recently disclosed stock data to emotional support. The goal, one might argue, is to form relationships with alters who can provide resources deemed advantageous by and for ego as compared to others. This entry discusses the advantages that alters can provide, reasons why alter relationships form and break apart, and how alter relationships function.

Alters, certainly, vary in the advantages (both tangible and intangible) that they can provide. Certain alters can provide advantages directly to ego. However, after engaging in social network analysis, it might very well be that it is not a direct alter who is most profitable for ego within his or her social network, but rather it is ego's alter's alter. That is to say, there is one degree of social separation between oneself and the social actor who can ultimately provide the very advantage in question.

As we likely know, we are part of a myriad of different, and likely nonoverlapping, networks of social alters. We are part of friend networks we are part of employee networks we are part of family networks we are part of college/college alumni networks we are part of Facebook networks we are part of neighborhood networks and the list goes on. While some alters might be linked to multiple networks and, as such, connect previously disconnected social alters together, much of the literature indicates that individuals purposefully create nonoverlapping social networks for purposes of exclusion.

Assume that Sara learns about a forthcoming Jon Bon Jovi concert, the tickets to which have been sold out for some time. Yet, we also learn that Gillian, a social alter part of Sara's neighborhood network, who is a social alter of Daniel's, who is a social alter of Sara's, knows of a work colleague trying to sell two tickets because her roommate was recently diagnosed with pneumonia and will not, as a result, be able to attend. Sara reaps the benefit of Gillian's work partner as a result of her connection with an alter (Daniel), which is predicated on his network connection with an alter (Gillian), which is, in the end, all based on her relationship with a colleague. The conclusion? Alters, as the literature claims, do not have to be directly connected to ego in order to provide benefits and resources. As long as ego is socially connected to alters who are connected to alters who are connected to alters who can provide something deemed important and necessary, then he or she has, from a social network perspective, immersed herself in a community rife with advantage and opportunity.

Alters also vary in the relational closeness that they share with ego himself or herself. It is both cognitively and behaviorally exhausting to create, develop, and maintain *strong* relationships with all of one's alters, and as research indicates, many of the ties that social actors create are *weak*: emblematic of infrequent communication with, and less emotional connection to, the alters part and parcel of one's social network(s). That said, of course, it is important not to confuse the word

weak with the semantic undertone of *unvaluable*. For such social activities as political rallying, health communication campaigns, and social justice movements, there is an important *strength* associated with *weak* alter ties.

Unfortunately, of course, not all relationships are able to survive for a multitude of different reasons. Alters change jobs alters engage in conflict that results in the dissolution of relationships alters decide to change networks based on mere free will alters move geographic locations and there are a multitude of additional independent variables coming to affect one's relationship with an alter. When alters, for whatever reason, depart from a larger social network, it might very well disrupt the entire social fabric of that socially constructed, socially connected community. This can be depicted by a sociogram, a pictorial representation of the ways in which a network's alters are connected to one another. Figure 1 shows an example of a sociogram.

The data used to determine these connections accrue by using what is known as the *name-generator technique*. In short, this involves asking social actors who they are likely to interact with when it comes to things such as information, gossip, entertainment, advice, and the like. If the line has two arrows, this implies reciprocity (meaning that both individuals are likely to communicate with each other), whereas a line with one arrow implies nonreciprocity (meaning that one individual is more likely to communicate with the alter as compared to the other). In the case

Figure 1 Eight-Person Sociogram Depicting Relationships Among Alters

shown in Figure 1, the question is what happens if an alter, for one reason or another, exits from this eight-person network?

As you can likely tell, Reesa is a very salient social alter within this network, as she has direct, reciprocal connections with five individuals: Hailey, Bradley, Joan, Kenneth, and Alexis. She, based on the empirical data, is the most important (central) member of this network. If she were to depart, several other social alters would be affected. For example, Reesa becomes the alter through which Alexis can communicate directly with Joan. If Reesa departs from this network, and Alexis wishes to interact with Joan, she is now forced to choose an entirely different social approach. She, in essence, would have to take an entirely different social path of connection (from Hailey to Bradley to Joan). While this might seem rather simple, research indicates that such a disruption in the configuration of alters has monumental implications for all affected social actors: especially those most important for the social connection of the network. Again, using the sociogram shown in Figure 1, if Jason and/or Michael were to depart, the implications would be much less severe, as the nonreciprocal connections that provide their connection to the network at large indicate that their departures would not be catastrophic at the macrolevel. They are both, according to the scholarly literature, considered social isolates and, as such, are likely to provide few (if any) necessary and desired resources to or for the network at large.

AMERICAN EDUCATIONAL RESEARCH ASSOCIATION

The American Educational Research Association (AERA) is an international professional organization, based in Washington, DC, dedicated to promoting research in the field of education. Through conferences, publications, and awards, AERA encourages the scientific pursuit and dissemination of knowledge in the educational arena. Its membership is diverse, drawing from within the education professions as well as from a broader social science background.

Mission

The mission of AERA is to influence the field of education in three major areas. Firstly, through improving knowledge about education. Secondly, through promoting educational research. Finally, through encouraging the use of educational research results to make education better and thereby improve the common good.

History

The AERA publicizes its founding as taking place in 1916. However, its roots have been traced back to the beginnings of the educational administration research area and the school survey movement, both of which took place in the 1910s. This new spirit of cooperation between university researchers and public schools led the way to the founding of the National Association of Directors of Educational Research (NADER) as an interest group by eight individuals, formed within the National Education Association (NEA) Department of Superintendence in February 1915. With the creation of its first organizational constitution in 1916, NADER committed itself to the improvement of public education through applied research. NADER's two goals were to organize educational research centers at public educational settings and to promote the use of appropriate educational measures and statistics in educational research. Full membership in this new organization was restricted to individuals who directed research bureaus, although others involved in educational research could join as associate members. NADER produced its first publication, the *Educational Research Bulletin*, in 1916. Within 3 years of its founding, membership had almost quadrupled to 36 full members. In 1919, two of the founders of NADER started producing a new journal, the *Journal of*

Educational Research (JER), soon to be adopted by NADER as an official publication.

With the growth in educational research programs in the late 1910s to early 1920s, NADER revised its constitution in 1921 to allow for full membership status to anyone involved in conducting and producing educational research, by invitation only, after approval from the Executive Committee. To better display this change in membership makeup, the group's name was changed in 1922 to the Educational Research Association of America (ERAA). This change in name also reflected a shift in the group's focus toward a broader representation of all who conducted educational research. This broader representation allowed for a large increase in membership, which grew to 329 members by 1931. Members were approximately two thirds from a university background and one third from the public schools. In 1928, ERAA changed its name, becoming the AERA.

After a problem involving the ownership of *JER*, AERA affiliated itself with the NEA in 1930, gaining Washington, DC, offices and support for AERA's proposed new journal. AERA underwent several changes during the 1930s. One change was the creation of their new journal, the *Review of Educational Research* (RER). Another was the decision to affiliate with other professional groups that shared common interests, such as the National Committee on Research in Secondary Education and the National Council of Education. The recognition of superior research articles at an annual awards ceremony was established in 1938. By 1940, AERA membership stood at 496.

Much of AERA's growth (beyond membership) has come from their journals. In 1950, the *AERA Newsletter* published its first issue. Its goal was to inform the membership about current news and events in education. Its name was changed to *Educational Researcher* in 1965. In 1963, the *American Educational Research Journal* (AERJ) was created to give educational researchers an outlet for publishing original research articles, as previous AERA publications focused primarily on reviews. By 1970, *RER* had changed the focus of its journal, which led to the creation of a new journal, the *Review of Research in Education* (RRE). In 2015, *AERA Open*, a peer-reviewed open-access journal, was created to encourage the rapid dissemination of new educational research.

AERA has been concerned with equity and civil rights both internally as an organization and externally in supplying resources for research-based policy advocacy. AERA was one of the last scholarly educational organizations to elect a person of color as president

with the election of Linda Darling-Hammond in 1995, although by its 100th anniversary in 2016, it had elected nine presidents of color. In 1995, the Task Force on the Role and Future of Minorities was formed to explore ways AERA could increase the opportunities for minority engagement within the organization. The late 1990s also saw the rise of more inclusive Annual Meeting themes and the addition of a director of social justice position. AERA has experienced a growth in diversity-related Special Interest Groups (SIGs) and has established awards, fellowships, and lecture programs related to diversity.

Organization of Association Governance

The organization of AERA has changed since its founding to accommodate the greater membership and its diverse interests. AERA is governed by a council, an executive board, standing committees, and award committees. AERA Council is responsible for policy setting for AERA and is formed of elected members including the president, president-elect, immediate past president, six at-large members, division vice presidents, a SIG representative, a graduate student representative, and the executive director. The council meets three to four times per year.

The Executive Board is an advisory board, which guides the president and executive director of AERA. The board meets three to four times per year. The board has managed elections, advised on the annual budget, and selected Annual Meeting sites, in addition to other needed tasks. Twenty-two current standing committees, appointed by the council, are charged with conducting specific tasks in accordance with AERA policy. These committees range in focus from the Annual Meeting Policies and Procedures Committee to the Journal Publications Committee to the Social Justice Action Committee.

Divisions

AERA has 12 scholarly or scientific areas of interest called *divisions*. Each AERA member selects one division to become a member of upon joining AERA. Members can belong to multiple divisions for an additional annual fee. Divisions hold business meetings as well as support the presentation of research in their interest area at the Annual Meeting. The 12 divisions are

Division A—Administration, Organization, & Leadership

Division B—Curriculum Studies

Division C—Learning & Instruction
 Division D—Measurement & Research Methodology
 Division E—Counseling & Human Development
 Division F—History & Historiography
 Division G—Social Context of Education
 Division H—Research, Evaluation, & Assessment in Schools
 Division I—Education in the Professions
 Division J—Postsecondary Education
 Division K—Teaching & Teacher Education
 Division L—Educational Policy & Politics

SIGs

SIGs are smaller groups within the AERA membership. These SIGs differ from divisions in that their focus tends to be on more specific topics than broad interests represented by divisions. Like divisions, SIGs hold business meetings and support presentations of research in their interest area at the Annual Meeting. There are approximately 155 SIGs registered with AERA. Membership is based on annual dues, which in 2020 ranged from US\$5 to US\$40. SIGs range in focus from Accreditation, Assessment, and Program Evaluation in Education Preparation (SIG #174) to Faculty Teaching, Evaluation, and Development (SIG #42) to Research on Giftedness, Creativity, and Talent (SIG #91). AERA members may join multiple SIGs. SIGs are represented by the SIG Executive Committee, and a member serves on the AERA Council and AERA Executive Board.

Membership

At over 25,000 members, AERA is among the largest professional organizations in the United States. Approximately 14% of members live outside the United States and 30% of its membership are students. Roughly 66% of its members are women. About 63% of the members hold a PhD or EdD, and 75% of its employed members work at a college/university. Membership in AERA is primarily divided among voting members and nonvoting affiliates. To be a voting member, one must either hold the equivalent of a master's degree or higher, be a graduate student sponsored by a voting member of their faculty, or be retired from a position eligible for membership. Nonvoting affiliate members are interested in educational research but do not have a high enough level of education, are undergraduate students who are sponsored by their faculty, or are non-U.S. citizens who do not meet the educational level

requirement. Students pay a reduced rate for membership. Members of AERA gain many benefits including a reduced cost to attend the Annual Meeting, free membership in one division, and free subscriptions to both the *Educational Researcher* and another AERA journal of their choice.

Publications

AERA publishes seven peer-reviewed journals as well as books and e-books. AERA's peer-reviewed journals include

AERJ

AERA Open

Educational Evaluation and Policy Analysis

Educational Researcher

Journal of Educational and Behavioral Statistics

RER

RRE

AERJ focuses on original scientific research in the field of education and learning. *AERA Open* is open access, covering similar material to the *AERJ*. *Educational Evaluation and Policy Analysis* publishes original research focusing on evaluation and policy analysis issues. *Educational Researcher* publishes information that is of general interest to a broader variety of AERA members. Interpretations and summaries of current educational research as well as book reviews make up the majority of its pages. The *Journal of Educational and Behavioral Statistics* focuses on new statistical methods for use in educational and behavioral research as well as critiques of current practices. It is published jointly with the American Statistical Association. *RER* publishes a variety of reviews of previously published educational articles by interested parties from varied backgrounds. *RRE* is an annual publication that solicits critical essays on a variety of topics facing the field of education.

Annual Meetings

AERA convenes a yearly Annual Meeting as an opportunity to bring AERA's membership together to discuss and debate the latest in educational practices and research. Approximately 16,000 attendees gather to listen, discuss, and learn over a 5-day period. For the 2019 meeting, 12,560 presentation proposals were submitted, and 6,279 papers were presented in 607 sessions. Presenters are invited to contribute a full-text paper to the AERA Online Paper Repository as a way to distribute their research more broadly. This online

repository is available open-access to the public. In addition to presentations, business meetings, invited sessions, awards, and demonstrations are held. Many graduate student-oriented sessions are also held. Sessions focusing on educational research related to the geographical location of the Annual Meeting are presented. Another valuable educational opportunity is the many professional development and training courses offered over the span of the conference. These tend to spotlight refresher courses in statistics and research design, evaluation, or workshops on new assessment tools or classroom-based activities.

In addition to the scheduled sessions, exhibitors of software, books, and testing materials present their wares at the exhibit hall, and those seeking new jobs can meet prospective employers in the career center. There are also tours of local attractions available. Each year's meeting is organized around a different theme. In 2020, the Annual Meeting theme was *The Power and Possibilities for the Public Good: When Researchers and Organizational Stakeholders Collaborate*. The Annual Meeting takes place in conjunction with the annual meeting of the National Council on Measurement in Education, which is held at the same time and place as AERA's meeting.

Other Services and Offerings

This section discusses several other AERA offerings, including the Graduate Student Council, awards, and fellowships and grants.

Graduate Student Council

Graduate students are supported through several programs within AERA, but the program that provides or sponsors the most offerings for graduate students is the Graduate Student Council. The council comprises two graduate student representatives from each division plus additional officers. Its mission is to support graduate student members during their transition to become professional researchers and/or practitioners through education and advocacy. The council sponsors many sessions at the Annual Meeting as well as publishing a newsletter multiple times per year.

Awards

AERA offers an extensive awards program, with 13 award committees overseeing the process. The recipients are announced at the President's Address during the Annual Meeting. AERA's divisions and SIGs also offer awards, which are recognized by AERA and presented during their group's business meeting. AERA's

awards cover educational researchers at all stages of their career, from the Early Career award to the Distinguished Contributions to Research in Education Award. Special awards are also given for other topics including social justice issues, public service, and outstanding books.

Fellowships and Grants

AERA offers fellowships, with special fellowships focusing on minority researchers and student researchers and a variety of fellowships on diverse areas of educational research. AERA also offers several small grants to support dissertations and other research.

AMERICAN PSYCHOLOGICAL ASSOCIATION STYLE

American Psychological Association (APA) style is a system of guidelines for writing and formatting manuscripts. APA style may be used for multiple types of manuscripts, such as theses, dissertations, reports of empirical studies, literature reviews, meta-analyses, theoretical articles, methodological articles, and case studies. APA style is described extensively in the *Publication Manual of the American Psychological Association* (APA Publication Manual). The APA Publication Manual includes recommendations on writing style,

grammar, and nonbiased language as well as guidelines for manuscript formatting, such as arrangement of tables and section headings. APA style is the most accepted writing and formatting style for journals and scholarly books in psychology as well as in other disciplines. The use of a single style that has been approved by the leading organization in the field aids readers, researchers, and students in organizing and understanding the information presented.

Writing Style

The APA style of writing emphasizes clear and direct prose. Ideas are to be presented in an orderly and logical manner, and writing is to be as concise as possible. APA style reinforces usual guidelines for clear writing, such as the presence of a topic sentence in each paragraph. Previous research is described in either the past tense (e.g., “Washington and Hamilton found”) or past perfect tense (e.g., “researchers have argued”). Past tense is used to describe procedures and results of an empirical study conducted by the author (e.g., “participants completed a survey,” “women scored higher than men”). Present tense (e.g., “these results indicate”) is used in discussing and interpreting results and drawing conclusions.

Nonbiased Language

APA style guidelines recommend that authors avoid language that is biased against particular individuals or groups. The APA provides specific guidelines for describing age, gender, race, ethnicity, sexual orientation, and disability status. Preferred terms change over time and may also be debated within groups; thus, authors are advised to consult a current style manual if they are unsure of which terms are currently preferred or considered offensive. Authors may also ask participants about terms they prefer for themselves.

General guidelines for avoiding biased language include being specific, employing person-first language, using labels as adjectives instead of nouns (e.g., *gay men* rather than *gays*), and avoiding labels that imply a hierarchy or standard of judgment (e.g., *normal development*, *stroke victim*).

Formatting

The APA Publication Manual provides extensive guidelines for formatting manuscripts. These include guidelines for use of numbers, abbreviations, quotations, and headings.

Tables and Figures

In many cases, tables and figures can present numerical information more clearly and concisely than would be possible in text. Tables and figures may also allow for greater ease in comparing numerical data (e.g., the mean achievement test scores of experimental and control groups). Figures and tables should present information clearly and supplement, rather than restate, information provided in the text of the manuscript.

Headings

Headings provide the reader with an outline of the organization of the manuscript. APA style includes five heading levels. Authors are advised to begin with the highest level of heading (Level 1) and continue as needed depending on the length and complexity of the manuscript. Most manuscripts will not require all five levels of heading. Topics of equal importance should have the same level of heading throughout the manuscript (e.g., the Method sections of multiple experiments should have the same heading level for each experiment). APA style recommends that author avoid using only one headed subsection within a section.

According to APA style, headings are formatted as follows:

Level 1: Centered Bold Uppercase and Lowercase Heading

Level 2: Flush Left Bold Uppercase and Lowercase Heading

Level 3: Flush Left Bold Italic Uppercase and Lowercase Heading

Level 4: Indented Bold Uppercase and Lowercase Heading Ending with a Period.

Level 5: Indented Bold Italic Uppercase and Lowercase Heading Ending with a Period.

For Heading Levels 1 through 3, the paragraph following the heading begins on a new line. For Heading Levels 4 and 5, the paragraph following the heading begins after the period at the end of the heading.

Manuscript Sections

A typical APA style manuscript reporting on an empirical study has five sections: Abstract, Introduction, Method, Results, and Discussion.

Abstract

An abstract is a concise (typically 100–250 words) summary of the contents of a manuscript. The abstract typically includes a description of the topic or problem

under investigation, information about participants and research methods, and the most important findings or conclusions. The abstract of a published article will often be included in databases; this allows researchers to search for relevant studies on a particular topic.

Introduction

The introduction section introduces the reader to the question under investigation. In this section, the author describes the topic or problem, discusses existing theory and research related to the topic, and states the purpose of the current study. The introduction typically concludes with a brief statement about the present study, including the author's research questions and/or hypotheses and the ways in which these research questions and hypotheses are supported by the existing research presented in the introduction.

Method

The method section describes how the study was conducted. The method section is frequently broken up into subsections, such as participants, procedure, and measures. Procedures and measures are described such that a reader knows what would be needed to replicate the study.

Descriptions of participants typically include summaries of demographic characteristics such as participants' ages, genders, and races and/or ethnicities. Other demographic characteristics, such as socioeconomic status and education level, are reported when relevant. The method by which participants were recruited (e.g., by newspaper advertisements or through a departmental subject pool) is also included.

The procedure describes participant recruitment, any experimental manipulation(s), instructions to participants (summarized unless instructions are part of the experimental manipulation, in which case they are presented verbatim), order in which measures and manipulations were presented, and control features (such as randomization and counterbalancing).

Measures that are commercially available or published elsewhere should be referred to by name and attributed to their authors, (e.g., "Self-esteem was measured using the Perceived Competence Scale for Children (Harter, 1982)."). Measures created for the current study should be described (e.g., example items, response scales) and may be reproduced in the manuscript in a table or appendix.

Results

The results section presents and summarizes the data collected and discusses the analyses conducted and their

results. Analyses are to be reported in sufficient detail to justify conclusions. All relevant analyses should be reported, even those whose results were statistically non-significant or that did not support the stated hypotheses.

For a quantitative study, the results section will typically include inferential statistics, such as chi-squares, *F* tests, or *t*-tests. For these statistics, the value of the test statistic, degrees of freedom, and *p* value should be reported (e.g., $F(1,75) = 4.60, p = .034$). Effect sizes for statistical tests are also frequently presented.

For a qualitative study, the results section will include descriptions of identified themes or data coding categories as well as descriptions of the data analysis procedures by which these themes or categories were identified. Qualitative research manuscripts may also include a description of the author's approach to inquiry (e.g., feminist, postmodern) and the author's own positionality relative to the research question and context.

The results section may include figures (such as graphs or models) and tables. Figures and tables will typically appear at the end of a manuscript. If the manuscript is being submitted for publication, notes may be included in the text to indicate where figures or tables are to be placed (e.g., "Insert Figure 1 here."). All figures and tables should be referenced in the manuscript text (e.g., "Scores for the intervention and control groups did not differ (see Table 2 for means).").

Discussion

In the discussion section, findings and analyses presented in the results section are summarized and interpreted. In this section, the author discusses how results relate to previously stated research questions and hypotheses. Conclusions are drawn but should remain within the boundaries of the data obtained. Ways in which the findings of the current study relate to the theoretical perspectives and prior research presented in the introduction also are typically addressed. In this section, authors also acknowledge the limitations of the current study. The discussion section may also address potential applications of the work or suggest future research.

Referring to Others' Work

It is an author's job to avoid plagiarism by noting when reference is made to another's work or ideas. This is true even when making general statements about existing knowledge (e.g., "Self-efficacy impacts many aspects of students' lives, including achievement motivation and task persistence (Bandura, 1997)."). Citations allow a reader to be aware of the original source of ideas or data and direct the reader toward sources of additional information on a topic.

In-Text Citations

Throughout the manuscript text, credit should be given to authors whose work is referenced. In-text citations allow the reader to be aware of the source of an idea and locate the work in the reference list at the end of the manuscript. APA style uses an author–date citation method; each in-text citation includes the author’s (or authors’) last name(s) and the year of publication. For works with two authors, both authors’ names are given. For works with three or more authors, the first author is listed by name followed by “et al.”, meaning “and others.” If multiple works are cited in a single in-text citation, they are listed alphabetically and separated with semicolons (e.g., Greenhoot et al., 2013; Rojas & Yoshikawa, 2017; Tucker, 2016). When a direct quotation from a source is presented, the page number of the quotation is presented along with the author and date (e.g., Bandura, 1997, p. 22).

Reference Lists

References are listed alphabetically by the last name of the first author. Citations in the reference list include names of authors, article or chapter title, journal or book title, and page numbers (if relevant). For sources accessed electronically, information regarding means of electronic access (web address or DOI) is provided. The APA Publication Manual includes guidelines for citing many different types of sources. Examples of some of the most common types of references appear below.

AMERICAN STATISTICAL ASSOCIATION

The American Statistical Association (ASA) is a society for scientists, statisticians, and statistics consumers representing a wide range of science and education fields. Since its inception in November 1839, the ASA has aimed to provide both statistical science professionals and the public with a standard of excellence for statistics-related projects. According to ASA publications, the society’s mission is “to promote excellence in the application of statistical science across the wealth of human endeavor.” Specifically, the ASA mission includes a dedication to excellence with regard to statistics in practice, research, and education; a desire to

work toward bettering statistical education and the profession of statistics as a whole; a concern for recognizing and addressing the needs of ASA members; education about the proper uses of statistics; and the promotion of human welfare through the use of statistics.

Regarded as the second-oldest, continuously operating professional association in the United States, the ASA has a rich history. In fact, within 2 years of its founding, the society already had a U.S. president—Martin Van Buren—among its members. Also on the list of the ASA's historical members are Florence Nightingale, Alexander Graham Bell, and Andrew Carnegie. The original founders, who united at the American Education Society in Boston to form the society, include U.S. Congressman Richard Fletcher; teacher and fundraiser William Cogswell; physician and medicine reformist John Dix Fisher; statistician, publisher, and distinguished public health author Lemuel Shattuck; and lawyer, clergyman, and poet Oliver Peabody. The founders named the new organization the American Statistical Society, a name that lasted only until the first official meeting in February 1840.

In its beginning years, the ASA developed a working relationship with the U.S. Census Bureau, offering recommendations and often lending its members as heads of the census. S. N. D. North, the 1910 president of the ASA, was also the first director of the permanent census office. The society, its membership, and its diversity in statistical activities grew rapidly after World War I as the employment of statistics in business and government gained popularity. At that time, large cities and universities began forming local chapters. By its 100th year in existence, the ASA had more members than it had ever had, and those involved with the society commemorated the centennial with celebrations in Boston and Philadelphia. However, by the time World War II was well underway, many of the benefits the ASA experienced from the post-World War I surge were reversed. For 2 years—1942 and 1943—the society was unable to hold annual meetings. Then, after World War II, as after World War I, the ASA saw a great expansion in both its membership and applications to burgeoning science endeavors.

Today, ASA has expanded beyond the United States and can count 18,000 individuals as members. Its members, who represent 78 geographic locations, also have diverse interests in statistics. These interests range from finding better ways to teach statistics to problem-solving for homelessness and from AIDS research to space exploration, among a wide array of applications. As an organization, the ASA frequently produces white papers and policy recommendations to guide the use of statistics in research. One instance is a 2020 report questioning the appropriateness of relying on levels of

significance when interpreting research results. Additionally, the organization frequently provides service and guidance for national and international governmental applications of statistical science. For example, the association's board published standards for statistical sampling quality for the U.S. 2020 Census.

The society comprises 24 sections, including the following: Bayesian Statistical Science, Biometrics, Biopharmaceutical Statistics, Business and Economic Statistics, Government Statistics, Health Policy Statistics, Nonparametric Statistics, Physical and Engineering Sciences, Quality and Productivity, Risk Analysis, Statistical Programmers and Analysts, Statistical Learning and Data Mining, Social Statistics, Statistical Computing, Statistical Consulting, Statistical Education, Statistical Graphics, Statistics and the Environment, Statistics in Defense and National Security, Statistics in Epidemiology, Statistics in Marketing, Statistics in Sports, Survey Research Methods, and Teaching of Statistics in the Health Sciences. Detailed descriptions of each section, lists of current officers within each section, and links to each section are available on the ASA website.

In addition to holding meetings coordinated by more than 60 committees of the society, the ASA sponsors scholarships, fellowships, workshops, and educational programs. Its leaders and members also advocate for statistics research funding and offer a host of career services and outreach projects.

Publications from the ASA include scholarly journals, statistical magazines, books, research guides, brochures, and conference proceeding publications. Among the journals available are *The American Statistician*; *Journal of Agricultural, Biological, and Environmental Statistics*; *Journal of the American Statistical Association*; *Journal of Business and Economic Statistics*; *Journal of Computational and Graphical Statistics*; *Journal of Educational and Behavioral Statistics*; *Journal of Statistics Education*; *Statistical Analysis and Data Mining*; *Statistics in Biopharmaceutical Research*; *Journal of Survey Statistics and Methodology*; and *Technometrics*.

The official website of the ASA offers a more comprehensive look at the mission, history, publications, activities, and future directions of the society. Additionally, browsers can find information about upcoming meetings and events, descriptions of outreach and initiatives, the ASA bylaws and constitution, a copy of the ethical guidelines for statistical practice prepared by the committee on professional ethics, and an organizational list of board members and leaders.

ANALYSIS OF COVARIANCE (ANCOVA)

Behavioral sciences rely heavily on experiments and quasi experiments for evaluating the effects of, for example, new therapies, instructional methods, or stimulus properties. An *experiment* includes at least two different treatments (conditions), and human participants are randomly assigned one treatment. If assignment is not based on randomization, the design is called a *quasi experiment*. The dependent variable or outcome of an experiment or a quasi experiment, denoted by Y here, is usually quantitative, such as the total score on a clinical questionnaire or the mean response time on a perceptual task. Treatments are evaluated by comparing them with respect to the mean of the outcome Y using either analysis of variance (ANOVA) or analysis of covariance (ANCOVA). Multiple linear regression may also be used, and categorical outcomes require other methods, such as logistic regression. This entry explains the purposes of, and assumptions behind, ANCOVA for the classical two-group between-subjects design. ANCOVA for within-subject and split-plot designs is discussed briefly at the end.

Researchers often want to control or adjust statistically for some independent variable that is not experimentally controlled, such as gender, age, or a pretest value of Y . A categorical variable such as gender can be included in ANOVA as an additional factor, turning a one-way ANOVA into a two-way ANOVA. A quantitative variable such as age or a pretest recording can be included as a covariate, turning ANOVA into ANCOVA. ANCOVA is the bridge from ANOVA to multiple regression. There are two reasons for including a

covariate in the analysis if it is predictive of the outcome Y . In randomized experiments, it reduces unexplained (within-group) outcome variance, thereby increasing the power of the treatment effect test and reducing the width of its confidence interval. In quasi experiments, it adjusts for a group difference with respect to that covariate, thereby adjusting the between-group difference on Y for confounding.

Model

The ANCOVA model for comparing two groups at posttest Y , using a covariate X , is as follows:

$$Y_{ij} = \mu + \alpha_j + \beta(X_{ij} - \bar{X}) + e_{ij}, \quad (1)$$

where Y_{ij} is the outcome for person i in group j (e.g., $j = 1$ for control, $j = 2$ for treated), and X_{ij} is the covariate value for person i in group j , μ is the grand mean of Y , α_j is the effect of treatment j , β is the slope of the regression line for predicting Y from X within groups, $\bar{X}$ is the overall sample mean of covariate X , and e_{ij} is a normally distributed residual or error term with a mean of zero and a variance σ_e^2 , which is the same in both groups. By definition, $\alpha_1 + \alpha_2 = 0$, and so $\alpha_2 - \alpha_1 = 2\alpha_2$ is the expected posttest group difference adjusted for the covariate X . This is even better seen by rewriting Equation 1 as

$$Y_{ij} - \beta(X_{ij} - \bar{X}) = \mu + \alpha_j + e_{ij} \quad (2)$$

showing that ANCOVA is ANOVA of Y adjusted for X . Due to the centering of X , that is, the subtraction of $\bar{X}$, the adjustment is on the average zero in the total sample. So the centering affects individual outcome values and group means, but not the total or grand mean μ of Y .

ANCOVA can also be written as a multiple regression model:

$$Y_{ij} = \beta_0 + \beta_1 G_{ij} + \beta_2 X_{ij} + e_{ij} \quad (3)$$

where G_{ij} is a binary indicator of treatment group ($G_{i1}=0$ for controls, $G_{i2}=1$ for treated), and β_2 is the slope β in Equation 3. Comparing Equation 1 with Equation 3 shows that $\beta_1 = 2\alpha_2$ and that $\beta_0 = (\mu - \alpha_2 - \beta\bar{X})$. Centering in Equation 3 both G and X (i.e., coding G as 1 and +1, and subtracting $\bar{X}$ from X) will give $\beta_0 = \mu$ and $\beta_1 = \alpha_2$. Application of ANCOVA requires estimation of β in Equation 1. Its

least squares solution is $\frac{\sigma_{XY}}{\sigma_X^2}$, the within-group covariance between pre- and posttest, divided by the within-group pretest variance, which in turn are both estimated from the sample.

Assumptions

As Equations 1 and 3 show, ANCOVA assumes that the covariate has a linear effect on the outcome and that this effect is homogeneous, the same in both groups. So there is no treatment by covariate interaction. Both the linearity and the homogeneity assumption can be tested and relaxed by adding to Equation 3 as predictors $X \times X$ and $G \times X$, respectively, but this entry concentrates on the classical model, Equation 1 or Equation 3. The assumption of homogeneity of residual variance σ_e^2 between groups can also be relaxed.

Another assumption is that X is not affected by the treatment. Otherwise, X must be treated as a mediator instead of as a covariate, with consequences for the interpretation of analysis with versus without adjustment for X . If X is measured before treatment assignment, this assumption is warranted.

A more complicated ANCOVA assumption is that X is measured without error, where *error* refers to intra-individual variation across replications. This assumption will be valid for a covariate such as age but not for a questionnaire or test score, in particular not for a pretest of the outcome at hand. Measurement error in X leads to *attenuation*, a decrease of its correlation with Y and of its slope β in Equation 1. This leads to a loss of power in randomized studies and to bias in nonrandomized studies.

A last ANCOVA assumption that is often mentioned, but not visible in Equation 1, is that there is no group difference on X . This seems to contradict one of the two purposes of ANCOVA, that is, adjustment for a group difference on the covariate. The answer is simple, however. The assumption is not required for covariates that are measured without measurement error, such as age. But if there is measurement error in X , then the resulting underestimation of its slope β in Equation 1 leads to biased treatment effect estimation in case of a group difference on X . An exception is the case of treatment assignment based on the observed covariate value. In that case, ANCOVA is unbiased in spite of measurement error in X , whether groups differ on X or not, and any attempt at correction for attenuation will then introduce bias. The assumption of no group difference on X is addressed in more detail in a special section on the use of a pretest of the outcome Y as covariate.

Purposes

The purpose of a covariate in ANOVA depends on the design. To understand this, note that ANCOVA gives

the following adjusted estimator of the group difference:

$$\hat{\Delta} = (\bar{Y}_2 - \bar{Y}_1) - \beta(\bar{X}_2 - \bar{X}_1). \quad (4)$$

In a randomized experiment, the group difference on the covariate, $(\bar{X}_1 - \bar{X}_2)$, is zero, and so the adjusted difference $\hat{\Delta}$ is equal to the unadjusted difference $(\bar{Y}_2 - \bar{Y}_1)$, apart from sampling error. In terms of ANOVA, the mean square (*MS*; treatment) is the same with or without adjustment, again apart from sampling error. Things are different for the *MS* (error), which is the denominator of the *F* test in ANOVA. ANCOVA estimates β such that the *MS* (error) is minimized, thereby maximizing the power of the *F* test. Since the standard error (*SE*) of $\hat{\Delta}$ is proportional to the square root of the *MS* (error), this *SE* is minimized, leading to more precise effect estimation by covariate adjustment.

In a nonrandomized study with groups differing on the covariate X , the covariate-adjusted group effect $\hat{\Delta}$ systematically differs from the unadjusted effect $(\bar{Y}_2 - \bar{Y}_1)$. It is unbiased if the ANCOVA assumptions are satisfied and treatment assignment is random conditional on the covariate, that is, random within each subgroup of persons who are homogeneous on the covariate. Although the *MS* (error) is again minimized by covariate adjustment, this does not imply that the *SE* of $\hat{\Delta}$ is reduced. This *SE* is a function not only of *MS* (error), but also of treatment–covariate correlation. In a randomized experiment, this correlation is zero apart from sampling error, and so the *SE* depends only on the *MS* (error) and sample size. In nonrandomized studies, the *SE* increases with treatment–covariate correlation and can be larger with than without adjustment. But in nonrandomized studies, the primary aim of covariate adjustment is correction for bias, not a gain of power.

The two purposes of ANCOVA are illustrated in Figures 1 and 2, showing the within-group regressions of outcome Y on covariate X , with the ellipses summarizing the scatter of individual persons around their group line. Each group has its own regression line with the same slope β (reflecting absence of interaction) but different intercepts. In Figure 1, of a nonrandomized study, the groups differ on the covariate. Moving the markers for both group means along their regression line to a common covariate value $\bar{X}$ gives the adjusted group difference $\hat{\Delta}$ on outcome Y , reflected by the vertical distance between the two lines, which is also the difference between both intercepts. In Figure 2, of a randomized study, the two groups have the same mean covariate value, and so unadjusted and adjusted group difference on Y are the

same. However, in both figures the adjustment has yet another effect, illustrated in Figure 2. The MS (error) of ANOVA without adjustment is the entire within-group variance in vertical direction, ignoring regression lines. The MS (error) of ANCOVA is the variance of the vertical distances of individual dots from their group regression line. All variation in the Y -direction that can be predicted from the covariate; that is, all increase of Y along the line is included in the unadjusted MS (error) but excluded from the adjusted MS (error), which is thus smaller. In fact, it is only $(1 - \rho_{XY}^2)$ as large as the unadjusted MS (error), where ρ_{XY} is the within-group correlation between outcome and covariate.

Figure 1 Adjustment of the Outcome Difference Between Groups for a Covariate Difference in a Nonrandomized Study

Notes: Regression lines for treated (upper) and untreated (lower) group. Ellipses indicate scatter of individuals around their group lines. Markers on the lines indicate unadjusted (solid) and adjusted (open) group means.

Figure 2 Reduction of Unexplained Outcome Variance by Covariate Adjustment in a Randomized Study

Notes: Vertical distance between upper and lower end of an ellipse indicates unexplained (within-group) outcome variance in ANOVA. Vertical distance within an ellipse indicates unexplained outcome variance in ANCOVA.

Using a Pretest of the Outcome as Covariate

An important special case of ANCOVA is that in which a pretest measurement of Y is used as covariate. The user can then choose between two methods of analysis:

1. ANCOVA with the pretest as covariate and the posttest as outcome.
2. ANOVA with the change score (posttest minus pretest) as outcome.

Two other popular methods come down to either of these two: ANCOVA of the change score is equivalent to Method 1. The Group $\times$ Time interaction test in a repeated measures ANOVA with pretest and posttest as repeated measures is equivalent to Method 2. So the choice is between Methods 1 and 2 only. Note that Method 2 is a special case of Method 1 in the sense that choosing $\beta = 1$ in ANCOVA gives ANOVA of change, as Equation 2 shows. In a randomized experiment, there is no pretest group difference, and both methods give the same unbiased treatment effect apart from sampling error, as Equation 4 shows. However, ANCOVA gives a smaller MS (error), leading to more test power and a smaller confidence interval than ANOVA of change, except if $\beta \approx 1$ in ANCOVA and the sample size N is small. In nonrandomized studies, the value for β in Equation 4 does matter, and ANCOVA gives a different treatment effect than does ANOVA of change. The two methods may even lead to contradictory conclusions, which is known as *Lord's ANCOVA paradox*. The choice between the two methods then depends on the assignment procedure. This is best seen by writing both as a repeated measures model.

ANOVA of change is equivalent to testing the Group $\times$ Time interaction in the following model (where regression weights are denoted by γ to distinguish them from the β s in earlier equations):

$$Y_{ijt} = \gamma_0 + \gamma_1 G_{ij} + \gamma_2 T_{it} + \gamma_3 G_{ij} T_{it} + e_{ijt} \quad (5)$$

Here, Y_{ijt} is the outcome value of person i in group j at time t , G is the treatment group (0 = control, 1 = treated), T is the time (0 = pretest, 1 = posttest), and e_{ijt} is a random person effect with an unknown 2×2 within-group covariance matrix Σ of pre- and posttest measures. By filling in the 0 or 1 values for G and T , one can see that γ_0 is the pretest (population) mean of the control group, γ_1 is the pretest mean difference between the groups, γ_2 is the mean change in the control group, and γ_3 is the difference in mean change between groups. Testing the interaction effect γ_3 in Equation 5

is therefore equivalent to testing the group effect on change ($Y - X$). The only difference between repeated measures ANOVA and Equation 5 is that ANOVA uses $(-1, +1)$ instead of $(0, 1)$ coding for G and T .

ANCOVA can be shown to be equivalent to testing γ_3 in Equation 5 after deleting the term $\gamma_1 G_{ij}$ by assuming $\gamma_1 = 0$, which can be done with mixed (multilevel) regression. So ANCOVA assumes that there is no group difference at pretest. This assumption is satisfied by either of two treatment assignment procedures: (1) randomization and (2) assignment based on the pretest X . Both designs start with one group of persons so that there can be no group effect at pretest. Groups are created after the pretest. This is why ANCOVA is the best method of analysis for both designs. In randomized experiments it has more power than ANOVA of change. With treatment assignment based on the pretest such that $\bar{X}_1 \neq \bar{X}_2$, ANCOVA is unbiased whereas ANOVA of change is then biased by ignoring regression to the mean. In contrast, if naturally occurring or preexisting groups are assigned, such as Community A getting some intervention and Community B serving as control, then ANCOVA will usually be biased whereas ANOVA of change may be unbiased. A sufficient set of conditions for ANOVA of change to be unbiased, then, is (a) that the groups are random samples from their respective populations and (b) that without treatment these populations change equally fast (or not at all). The bias in ANCOVA for this design is related to the issue of underestimation of β in Equation 1 due to measurement error in the covariate. Correction for this underestimation gives, under certain conditions, ANOVA of change. In the end, however, the correct method of analysis for nonrandomized studies of preexisting groups is a complicated problem because of the risk of hidden confounders. Having two pretests with a suitable time interval and two control groups is then recommended to test the validity of both methods of analysis. More specifically, treating the second pretest as posttest or treating the second control group as experimental group should not yield a significant group effect because there is no treatment.

Covariates in Other Popular Designs

This section discusses covariates in within-subject designs (e.g., *crossovers*) and between-subject designs with repeated measures (i.e., a *split-plot design*).

A within-subject design with a quantitative outcome can be analyzed with repeated measures ANOVA, which reduces to Student's paired t test if there are only two treatment conditions. If a covariate such as age or a factor such as gender is added, then repeated

measures ANOVA with two treatments comes down to applying ANCOVA twice: (1) to the within-subject difference D of both measurements (within-subject part of the ANOVA) and (2) to the within-subject average A of both measurements (between-subject part of the ANOVA). ANCOVA of A tests the main effects of age and gender. ANCOVA of D tests the Treatment $\times$ Gender and Treatment $\times$ Age interactions and the main effect of treatment. If gender and age are centered as in Equation 1, this main effect is μ in Equation 1, the grand mean of D . If gender and age are not centered, as in Equation 3, the grand mean of D equals $\beta_0 + \beta_1 \bar{G} + \beta_2 \bar{X}$, where G is now gender and X is age. The most popular software, SPSS (an IBM company, formerly called PASW[®] Statistics), centers factors (here, gender) but not covariates (here, age) and tests the significance of β_0 instead of the grand mean of D when reporting the F test of the within-subject main effect. The optional pairwise comparison test in SPSS tests the grand mean of D , however.

Between-subject designs with repeated measures, for example, at posttest and follow-ups or during and after treatment, also allow covariates. The analysis is the same as for the within-subject design extended with gender and age. But interest now is in the Treatment (between-subject) $\times$ Time (within-subject) interaction and, if there is no such interaction, in the main effect of treatment averaged across the repeated measures, rather than in the main effect of the within-subject factor time. A pretest recording can again be included as covariate or as repeated measure, depending on the treatment assignment procedure. Note, however, that as the number of repeated measures increases, the F test of the Treatment $\times$ Time interaction may have low power. More powerful are the Treatment $\times$ Linear (or Quadratic) Time effect test and discriminant analysis.

Within-subject and repeated measures designs can have not only between-subject covariates such as age but also within-subject or time-dependent covariates. Examples are a baseline recording within each treatment of a crossover trial, and repeated measures of a mediator. The statistical analysis of such covariates is beyond the scope of this entry, requiring advanced methods such as mixed (multilevel) regression or structural equations modeling, although the case of only two repeated measures allows a simpler analysis by using as covariates the within-subject average and difference of the original covariate.

Practical Recommendations for the Analysis of Studies With Covariates

Based on the preceding text, the following recommendations can be given: In randomized studies, covariates

should be included to gain power, notably a pretest of the outcome. Researchers are advised to center covariates and check linearity and absence of treatment-covariate interaction as well as normality and homogeneity of variance of the residuals. In nonrandomized studies of preexisting groups, researchers should adjust for covariates that are related to the outcome to reduce bias. With two pretests or two control groups, researchers should check the validity of ANCOVA and ANOVA of change by treating the second pretest as posttest or the second control group as experimental group. No group effect should then be found. In the real posttest analysis, researchers are advised to use the average of both pretests as covariate since this average suffers less from attenuation by measurement error. In nonrandomized studies with only one pretest and one control group, researchers should apply ANCOVA and ANOVA of change and pray that they lead to the same conclusion, differing in details only.

Additionally, if there is substantial dropout related to treatment or covariates, then all data should be included in the analysis to prevent bias, using mixed (multilevel) regression instead of traditional ANOVA to prevent listwise deletion of dropouts. Further, if pretest data are used as an inclusion criterion in a nonrandomized study, then the pretest data of all excluded persons should be included in the effect analysis by mixed regression to reduce bias.

ANALYSIS OF VARIANCE (ANOVA)

Usually a two-sample *t* test is applied to test for a significant difference between two population means based on the two samples. For example, consider the data in Table 1. Twenty patients with high blood pressure are randomly assigned to two groups of 10 patients. Patients in Group 1 are assigned to receive placebo, while patients in Group 2 are assigned to receive Drug A. Patients' systolic blood pressures (SBPs) are measured before and after treatment, and the differences in SBPs are recorded in Table 1. A two-sample *t* test would be an efficient method for testing the hypothesis that drug A is more effective than placebo when the differences in before and after measurements are normally distributed. However, there are usually more than two groups involved for comparison in many fields of scientific investigation. For example, extend the data in Table 1 to the data in Table 2. Here the study used 30 patients who are randomly assigned to placebo, Drug A, and Drug B. The goal here is to compare the effects of placebo and experimental drugs in reducing SBP. But a two-sample *t* test is not applicable here as we have more than two groups. Analysis

0.3	-0.5
-2.2	-3.3

of variance (ANOVA) generalizes the idea of the two-sample t test so that normally distributed responses can be compared across categories of one or more factors.

Since its development, ANOVA has played an indispensable role in the application of statistics in many fields, such as biology, social sciences, finance, pharmaceuticals, and scientific and industrial research. Although ANOVA can be applied to various statistical models, and the simpler ones are usually named after the number of categorical variables, the concept of ANOVA is based solely on identifying the contribution of individual factors in the total variability of the data. In the above example, if the variability in SBP changes due to the drug is large compared with the chance variability, then one would think that the effect of the drug on SBP is substantial. The factors could be different individual characteristics, such as age, sex, race, occupation, social class, and treatment group, and the significant differences between the levels of these factors can be assessed by forming the ratio of the variability due to the factor itself and that due to chance only.

History

As early as 1925, R. A. Fisher first defined the methodology of ANOVA as “separation of the variance ascribable to one group of causes from the variance ascribable to other groups” (p. 216). Henry Scheffé defined ANOVA as “a statistical technique for analyzing measurements depending on several kinds of effects

operating simultaneously, to decide which kinds of effects are important and to estimate the effects. The measurements or observations may be in an experimental science like genetics or a nonexperimental one like astronomy” (p. 3). At first, this methodology focused more on comparing the means while treating variability as a nuisance. Nonetheless, since its introduction, ANOVA has become the most widely used statistical methodology for testing the significance of treatment effects.

Based on the number of categorical variables, ANOVA can be distinguished into one-way ANOVA and two-way ANOVA. Besides, ANOVA models can also be separated into a fixed-effects model, a random-effects model, and a mixed model based on how the factors are chosen during data collection. Each of them is described separately.

One-Way ANOVA

One-way ANOVA is used to assess the effect of a single factor on a single response variable. When the factor is a fixed factor whose levels are the only ones of interest, one-way ANOVA is also referred to as fixed-effects one-way ANOVA. When the factor is a random factor whose levels can be considered as a sample from the population of levels, one-way ANOVA is referred to as random-effects one-way ANOVA. Fixed-effects one-way ANOVA is applied to answer the question of whether the population means are equal or not.

Table 2 Comparison of Three Treatments Based on Systolic Blood Pressure Change

<i>Placebo</i>	<i>Drug A</i>	<i>Drug B</i>
-1.3	-4.0	-7.6
0.5	-5.7	-9.2
-0.5	-3.5	-4.0
0.4	0.4	1.8
-1.1	-1.3	-5.3
0.6	0.8	2.6
-0.8	-10.7	-3.8
-3.6	-0.3	1.2
0.3	-0.5	0.4
-2.2	-3.3	-2.6

Given k population means, the null hypothesis can be written as

$$H_0 : \mu_1 = \mu_2 = \dots = \mu_k \quad (1)$$

The alternative hypothesis, H_a , can be written as
Ha : k population means are not all equal

In the random-effects one-way ANOVA model, the null hypothesis tested is that the random effect has zero variability.

Four assumptions must be met for applying ANOVA:

A1: All samples are simple random samples drawn from each of k populations representing k categories of a factor.

A2: Observations are independent of one another.

A3: The dependent variable is normally distributed in each population.

A4: The variance of the dependent variable is the same in each population.

Suppose, for the j th group, the data consist of the n_j measurements $Y_{j1}, Y_{j2}, \dots, Y_{jn_j}, j = 1, 2, \dots, k$. Then the total variation in the data can be expressed as the corrected sum of squares (SS) as follows: $TSS = \sum_{j=1}^k \sum_{i=1}^{n_j} (Y_{ji} - \bar{y})^2$, where $\bar{y}$ is the mean of the overall sample. On the other hand, variation due to the factor is given by

$$SST = \sum_{j=1}^k (\bar{y}_j - \bar{y})^2, \quad (2)$$

where $\bar{y}_j$ is the mean from the j th group. The variation due to chance (error) is then calculated as SSE (error sum of squares) = $TSS - SST$. The component variations are usually presented in a table with corresponding degrees of freedom (df), mean square error, and F statistic. A table for one-way ANOVA is shown in Table 3.

For a given level of significance α , the null hypothesis H_0 would be rejected and one could conclude that k population means are not all equal if

$$F \geq F_{k-1, n-k, 1-\alpha} \quad (3)$$

where $F_{k-1, n-k, 1-\alpha}$ is the $100(1-\alpha)\%$ point of F distribution with $k-1$ and $n-k$ df .

Two-Way ANOVA

Two-way ANOVA is used to assess the effects of two factors and their interaction on a single response variable. There are three cases to be considered: the

Table 3 General ANOVA Table for One-Way ANOVA (k populations)

Source	d.f.	SS	MS	F
Between	$k - 1$	SST	$MST = \frac{SST}{k-1}$	$\frac{MST}{MSE}$
Within	$n - k$	SSE	$MSE = \frac{SSE}{n-k}$	
Total	$n - 1$	TSS		

Note: n =sample size; k =number of groups; SST =sum of squares treatment (factor); MST =mean square treatment (factor); SSE =sum of squares error; TSS =total sum of squares.

fixed-effects case, in which both factors are fixed; the random-effects case, in which both factors are random; and the mixed-effects case, in which one factor is fixed and the other factor is random. Two-way ANOVA is applied to answer the question of whether Factor A has a significant effect on the response adjusted for Factor B, whether Factor B has a significant effect on the response adjusted for Factor A, or whether there is an interaction effect between Factor A and Factor B.

All null hypotheses can be written as

1. H_{01} There is no Factor A effect.
2. H_{02} There is no Factor B effect.
3. H_{03} There is no interaction effect between Factor A and Factor B.

The ANOVA table for two-way ANOVA is shown in Table 4.

In the fixed case, for a given α , the null hypothesis H_{01} would be rejected, and one could conclude that there is a significant effect of Factor A if

$$F(\text{Factor A}) \geq F_{r-1, rc(n-1), 1-\alpha}, \quad (4)$$

where $F_{r-1, rc(n-1), 1-\alpha}$ is the $100(1-\alpha)\%$ point of F distribution with $r-1$ and $rc(n-1)$ df .

The null hypothesis H_{02} would be rejected, and one could conclude that there is a significant effect of Factor B if

$$F(\text{Factor B}) \geq F_{c-1, rc(n-1), 1-\alpha} \quad (5)$$

where $F_{c-1, rc(n-1), 1-\alpha}$ is the $100(1-\alpha)\%$ point of F distribution with $c-1$ and $rc(n-1)$ df .

Factor A (main effect)	$r - 1$	SSR	$MSR = \frac{SSR}{r - 1}$	$\frac{MSR}{MSE}$	$\frac{MSR}{MSRC}$
Factor B (main effect)	$c - 1$	SSC	$MSC = \frac{SSC}{c - 1}$	$\frac{MSC}{MSE}$	$\frac{MSC}{MSRC}$
Factor A X Factor B (interaction)	$(r - 1)(c - 1)$	SSRC	$MSRC = \frac{SSRC}{(r - 1)(c - 1)}$	$\frac{MSRC}{MSE}$	$\frac{MSRC}{MSE}$
Error	$rc(n - 1)$	SSE	$MSE = \frac{SSE}{rc(n - 1)}$		
Total	$rcn - 1$	TSS			

Note: r =number of groups for A; c =number of groups for B; SSR=sum of squares for Factor A; MSR=mean sum of squares for Factor A; MSRC=mean sum of squares for the Interaction AxB; SSC=sum of squares for Factor B; MSC=mean square for Factor B; SSRC=sum of squares for the Interaction AxB; SSE=sum of squares error; TSS=total sum of squares.

The null hypothesis H_{03} would be rejected, and one could conclude that there is a significant effect of interaction between Factor A and Factor B if

$$F(\text{Factor A} \times \text{Factor B}) \geq F_{(r-1)(c-1), rc(n-1), 1-\alpha} \quad (6)$$

where $F_{(r-1)(c-1), rc(n-1), 1-\alpha}$ is the 100(1- α)% point of F distribution with $(r - 1)(c - 1)$ and $rc(n - 1)$ df.

It is similar in the random case, except for different F statistics and different df for the denominator for testing H_{01} and H_{02} .

Statistical Packages

SAS procedure “PROC ANOVA” performs ANOVA for balanced data from a wide variety of experimental designs. The “anova” command in STATA fits ANOVA and analysis of covariance (ANCOVA) models for balanced and unbalanced designs, including designs with missing cells; models for repeated measures ANOVA; and models for factorial, nested, or mixed designs. The “anova” function in S-PLUS produces a table with rows corresponding to each of the terms in the object, plus an additional row for the residuals. When two or more objects are used in the call, a similar table is produced showing the effects of the pairwise differences between the models, considered sequentially from the first to the last. SPSS (an IBM company, formerly called

PASW® Statistics) provides a range of ANOVA options, including automated follow-up comparisons and calculations of effect size estimates.

ANIMAL RESEARCH

Animal research refers to any investigation that includes animals as the research subject or population in an investigation; therefore, there is no specific theory that

supports all animal research. The term *animal research* refers only to the sample, not the mechanism or the method. Animal research may be basic and/or applied, it might be direct—to better understand the animal species of interest—or it could be comparative, wherein the animal is used as a model for another species. In addition, animal research occurs in differing contexts, which might include the animal's natural habitat, like field settings, in an artificial natural habitat, like zoological gardens and aquariums, or in purely captive environs, like laboratory or agricultural settings. The empirical question and the context in which the research occurs influences the research design employed and thereby how much control is exerted on the behavior, physiology, or genetics of the animal subject or subjects. This entry discusses animal research regulations and ethics and then provides insight and examples of descriptive and experimental animal research, which are the two most commonly used designs in animal research.

Regulation and Ethics in Animal Research

Although there are several layers of animal research regulation in the United States, and these regulations and guiding principles differ internationally, most countries follow the practice referred to as the 3 Rs: reduction, refinement, and replacement. The 3 Rs refer to limiting the number of animals subject to disturbance in research (i.e., reduction), improving procedures and protocols to minimize or eliminate pain and stress to animals (i.e., refinement), and to, wherever possible, use computer simulations or alternatives to animals in research projects (i.e., replacement). Animal research is often defined along continuums from non-intrusive to noninvasive, from noninvasive to intrusive, and from intrusive to invasive. Along with that continuum of disturbance or harm, the least intrusive is descriptive research, which occurs in the animal's natural habitat with little to no behavioral disruption. The most invasive may involve genetic or physiological manipulation through experimentation to solve applied problems like cancer, infertility, and disease.

Regardless of whether animal research is descriptive, involving no direct interaction with the animal and thereby constraining data collection to behavioral observation, or biomedical, such that the animal is the recipient of a manipulation either within a control or a treatment condition, all animal research requires ethical and regulatory oversight. In the United States, there are five formal levels of oversight governing animal research, including the Animal Welfare Act (AWA), the

Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals, Institutional Animal Care and Use Committees (IACUC), the Association for Assessment and Accreditation of Laboratory Animal Care International, and the U.S. Department of Agriculture. These five levels do not include local and state regulations, and private accrediting bodies (e.g., Association of Zoos and Aquariums) that may have their own formalized expectations and laws governing animal care.

The AWA, enacted in 1966, has been amended four times (1970, 1976, 1985, and 1991), each modification elevating the ethical standards regulating the use of animals in research, exhibition, and transport. The most significant revision occurred in 1985, resulting in the establishment of an Animal Welfare Information Center, providing a database for alternatives to animal experiments, and the formalization of an IACUC at all research facilities associated with laboratories, zoos, aquariums, and academic institutions. It is the responsibility of each facility's IACUC to review all protocols involving nonhuman, endothermic (i.e., excludes fish, amphibians, and reptiles) vertebrate animals for ethical compliance. Even field studies that do not involve invasive procedures, harm, or materially alter the behavior of an animal under study are still subject to IACUC review for exemption status.

The ethical guidelines governing the ethics evaluated through IACUC is the *Guide for the Care and Use of Laboratory Animals* (including fish, amphibians, and reptiles), referred to as *The Guide*. Published by the National Research Council and the Institute for Laboratory Animal Research, *The Guide's* recommendations for the humane care and use of laboratory animals are enforceable through the Health Research Extension Act (HREA). HREA reflects the third level of animal ethics oversight and was passed by Congress in 1985, establishing the PHS Policy on Human Care and Use of Laboratory Animals. HREA asserts that any research facility that receives PHS funds must provide a written plan that complies with the PHS policy and with guidelines set forth in *The Guide*, which is also the basis for the fourth level of oversight governing animal research, the Association for Assessment and Accreditation of Laboratory Animal Care International, a non-profit organization founded to promote uniform standards of animal care in U.S. laboratories including those accredited throughout the world. The final governing body in the United States, the U.S. Department of Agriculture, is responsible for the enforcement of animal ethics compliance through the AWA, specifically as it relates to animals in agriculture (i.e., livestock), domestic and companion animals (i.e., pets), and licensure of animal research facilities.

Descriptive Animal Research

The least invasive animal research is descriptive, with the most indirect animal investigation involving phylogenies. This method, referred to as the *comparative method*, examines the evolutionary origin of a species' morphological or behavioral traits. Data collected using the comparative phylogenetic method may include fossil evidence, archival documents, genetic fingerprinting, bones, behavioral activity budgets, and catalogs, called *ethograms*. Although descriptive observation dates back as far as 40,000 years ago through the depiction of a bull in Lubang Jeriji Saléh cave in East Kalimantan, Borneo, the most cited descriptive animal research began in the early 1960s. Jane Goodall, one of three mentees under paleoanthropologist Louis Leakey, which included Dian Fossey, who studied mountain gorillas in Volcanoes National Park, Rwanda, and Biruté Galdikas, whose subject was orangutans in Tanjung Puting Reserve, in Indonesian Borneo. Goodall, using field observation, ethograms for cataloging behavior, and family pedigrees, established the first objective field protocols for the study of animal behavior. Simple field observation techniques are still in practice, although often in place of investigators, remote cameras, drones, and infrared capture systems are frequently in use to further limit disruption to the animal's natural behavior.

Descriptive field research of animal distribution, density, and migration may involve more intrusive methods for data collection. Territorial range, diving depths, breathing delay, travel routes, and travel speed reflect the dependent variable and may involve radio telemetry, other tracking equipment, and animal transmitters. Depending on the animal target, the transmitter attachments can vary from mildly intrusive, like those data loggers affixed to the dorsal surface of whales using a long pole and suction, or invasive, wherein the animal is darted or shot with a tranquilizer or fitted for either external transmitters through collars, tail, or ear tags, or internal implants. The transmitters may stay with the animal through their life span or break away to be collected in the field. Other descriptive data that can be collected through nonintrusive means include specimen samples from animals like shed fur, hair, scales, cuticles, carapaces, skin, fecal samples, and carcass salvage. The biological data obtained from passive field sampling can provide information about diet, endocrine function, pollutant exposure, genetic diversity, pedigree, and speciation.

In addition to descriptive research in animals' natural habitat, zoological gardens and aquariums provide an important environmental context for

descriptive studies, especially those involving animal welfare, education, rehabilitation, and conservation. Beginning in the late 18th century, zoological gardens or parks (i.e., zoos) served to inspire and entertain, providing a glimpse into the diversity and scope of the world's animals. By the 20th century, the focus on entertainment was shared with education and conservation, wherein many zoos established nonprofit foundations to accept injured or orphaned animals with the goal of rehabilitation and reintroduction to their natural habitat. In these environs, descriptive animal research aims to provide approximations of a natural habitat to encourage biologically predisposed behavior that occur in natural habitats despite the artificial context. Thus, ethograms or behavioral catalogs and activity budgets may include species-typical behavior as well as stereotypies (i.e., repetition of movements or sounds). Stereotypies combined with steroid hormones and glucocorticoid function are common welfare metrics and refer to unvarying, ritualistic behavior or sequences of behavior that include self-stimulation, movement, or ingestion of inedible objects. These behavioral ethograms and activity budgets are then used to understand, improve, and implement species-specific enrichment, husbandry, and exhibit space.

Experimental Animal Research

Experiments reflect the greatest level of control in a research design, wherein the animal subject is randomly assigned to two or more treatment conditions of an independent variable. These studies most often occur in a laboratory, agricultural area, or some other captive context wherein the conditions of the independent variable and associated intervening variables such as temperature, time of day, conspecific exposure, sensory stimuli, and so on can be carefully controlled.

The dependent variable of experimental animal studies may involve behavioral, physiological, genetic, neural, or immune changes. The least disturbance among animal experiments is noninvasive behavioral studies, like those of early ethologists who studied animal social behavioral patterns and their releasing mechanisms. Examples of more invasive animal experimental research involve pathological studies and virology, wherein ultimately the animal subject must be sacrificed to evaluate the methodological outcomes. In fact, virtually all major medical treatments involve the use of animal subjects at some stage of the research. The use of animals in biomedical studies hinge on four main goals: (1) to improve our understanding of biology, (2) to better understand pathology and disease,

(3) to test new vaccines and treatments, and (4) to protect humans and other animals. Although initially tested using in vitro methods on isolated tissues and organs, medical trials are required by law to be ethically tested on a suitable animal model before human clinical trials. The gold standard for such research is placebo-controlled trials on animals, concluding in placebo-controlled, double-blind studies among human participants. For studies conducted to *protect humans and other animals*, these may involve commercial product testing, like those in the cosmetic industry, although greater public awareness and better ethical regulations have limited much of the use of animals in product testing.

ANONYMITY

In research design, anonymity refers to the concept of removing identifying features and characteristics to make the source of information unknown. The concept requires that the receiver of information is left without clues to the identity of the source because the typical identifying information is removed. This anonymity process can be completed by the sender or the source of the information. Anonymity is typically required or requested in cases where knowing the identity of the source would change the results of a study, change the treatment of the information, or change the use of any analysis. This entry discusses factors that can be used to identify research participants, the purpose of

anonymity in research, how individuals' perceptions of anonymity can affect behavior, and anonymity in the online environment.

Identifying Factors

In research design, granting participants anonymity requires removing identifying factors from information. Identifying factors include (1) legal name, (2) locatability, (3) pseudonyms, (4) social categorization, (5) pattern knowledge, and (6) symbols of eligibility. Each of these must be removed from information to guarantee anonymity.

First, the primary source of identifying information is the legal name of the sender. A legal name is one that is documented through government or regulatory procedures such as a birth certificate or passport. When legal names are attached to information, they are easy to identify and trace back to the source.

Second, locatability refers to the connection of information to a specific location or place. Locatability allows the receiver to trace information to a location such as an address, a region, or nation, which provides insight into the source of the information. This type of identity can be used alongside other types to identify the source of information. For example, a geotag on a social media post can be used to identify the location of a user when posting information online.

Third, pseudonyms are nicknames that are either adopted by the source or given to the source by others. Like a legal name, pseudonyms are often documented and therefore traceable. For example, a username on a social media website is a pseudonym that can be linked to an email address or other forms of identifying information.

Fourth, social categorization is data related to the demographics or psychographics of a source of information. This includes information on gender, race/ethnicity, age, employment, income, and political or religious orientation, among other categories. Social categorization data can be traced back to a specific individual based on cross-referencing categories.

Fifth, pattern knowledge refers to the ability to cross-reference categories and content found within the information to identify the source. For example, if a data set included quotes from individuals, familiar speech patterns or phrasing could be used to identify the source, assuming the researcher has outside knowledge or interactions with the individual.

Finally, symbols of eligibility include culturally negotiated symbols. Typical symbols include wedding bands, logos, and tattoos. These symbols can be used to segment possible sources of information by matching the symbol with an individual's potential identity.

Importantly, these six factors can be used independently or in concert with each other, meaning information that is not properly anonymized can be traced back to a source if any of these factors are present. The more factors or more specific the factor, the easier it is to trace someone's identity.

Purpose of Anonymity

Anonymity is often a requirement for scholarly research, journalism, and criminal justice. There are many reasons why a source of information would wish to remain anonymous as well as why the receiver of the information would want the source to be anonymous.

In scholarly research, institutional review boards often require data be anonymized before a researcher accesses it for analysis. It is required to both protect the identity of the source and ensure more reliable analysis. Many studies, particularly those looking at sensitive information such as medical records, psychological responses, and even communicative patterns, require anonymity to protect the identity of the source. Without this anonymity, the information provided by the source might be used by individuals outside the research setting and the source might face retribution. For example, studies examining political opinions often require anonymity so that the sources' personal preferences are not exposed to unsupportive users.

Anonymity is also viewed as a way to enhance the reliability of findings. Participants who are ensured that their data and identity will be anonymous may be more likely to share authentic or accurate information without fear of exposure or retribution. For example, participants asked about their political views and who are not guaranteed anonymity may change (intentionally or unintentionally) their responses to questions to meet the expectations and biases of the researchers. However, anonymity is also a legal condition that is granted to participants after informed consent. Institutions that approve of a researcher's project and protocol also offer legal protections for participants who may share sensitive information through a study. For example, should a research study require participants to share information about illegal behaviors, the institution can provide legal protection and prevent the researcher from having to share identifying information to law enforcement. It is for this reason that institutional review boards often spend additional time reviewing proposals that may require legal interventions to protect subject anonymity.

Closely related to the reviewing of research protocols and anonymity are the actions taken when a participant becomes a whistleblower regarding unethical or illegal research activities. Institutions grant

anonymity to whistleblowers to encourage their honesty and to protect them from potential backlash. In the research process, this may mean a study's subject reports unethical behaviors of researchers to an institutional review board, which then investigates the allegations. Protecting the participant's identity helps ensure that the whistleblower remains safe and feels comfortable sharing details of the problems.

Finally, anonymity is also a condition of the peer-review process or the practice of having other researchers evaluate potential conference and journal publications. In a traditional double-blind peer-review process, both the identity of the author and reviewer are kept anonymous to prevent any preexisting perceptions of the other person or the relationship between the two parties from clouding the quality of the review.

Anonymity and Behavior

The psychological state associated with perceived anonymity is linked to the reduction in inhibitions and the enhancement of some behaviors. For example, an individual may be more likely to adopt behaviors that they may otherwise avoid when in a large crowd because they are with other people and therefore less likely to be called out individually or identified. When an individual is at a concert venue, they are more likely to sing and dance along to the music, even if they would normally avoid doing those things in public. The perception of anonymity makes individuals feel as if they can act without being identified or without facing retaliation.

This psychological reaction to anonymity appears in other forms of crowds such as riots. When surrounded by a large crowd and an individual feels they cannot be singularly identified, they may be more likely to adopt violent or destructive behaviors. In these cases, the perception of anonymity is linked to the reduction of retaliation and consequences. This is often deemed a "crowd mentality" because rather than perceiving themselves as an individual, the person identifies as part of the crowd and feels they are helping to carry out the goals of the group.

When an individual is identified after perceiving themselves as anonymous, they often experience shock. The psychological feelings associated with anonymity are so powerful, that when it is violated by external identification, individuals often have a difficult time defending or acknowledging their actions.

Digital Anonymity

Anonymity online is often a challenging feature to those running digital platforms, studying digital

behavior, or regulating digital content as well as to users themselves. For those running digital platforms, user anonymity can make it difficult to gain insight into the types of people who regularly interact with their platforms. For example, when users create accounts, they can fill in information that is inaccurate or limit the information provided. Most platforms require verified email addresses but do not verify other identifying factors such as legal name, address, or identity characteristics. As a result, those running digital platforms are often left with unreliable or incomplete data on users.

For those managing online content, anonymity is particularly problematic when users act outside the boundaries of normal or acceptable behavior online. Trolling behavior, when an individual posts incendiary comments to motivate reactions, often requires intervention from digital platform managers. However, without insight into the identity of the user, it can be difficult to create long-term solutions such as banning the individual.

For those studying online behavior, user anonymity challenges the insights gathered from data analysis. For example, Twitter researchers who study how users adopt a specific hashtag are limited by the amount of information provided by users. Even when working directly with Twitter, identifying details are often unverified, often producing a gap in the research.

For users themselves, perceived anonymity can also challenge digital engagement and behaviors. Organizations and platforms can use myriad programs to collect identifying information—often without the users' direct knowledge. For example, one form of identity tracker still used today includes “cookie” programs allowing organizations to track how users progress through the internet and relay information about website use and browsing history back to central data warehouses. Although most users accept end-user license agreements that document and explain this tracking, many users are still unaware of how that data can be used to harvest identifiable information. Other tracking programs and software can similarly archive identifying information ranging from name, location, credit card and financial information, personal interests and preferences, and education history. Even if a user agrees to the use of cookies when going on a website, the user may still feel anonymous but is instead easily identifiable.

Anonymity online is still a relatively new topic, one that requires more research to understand how it may impact user and platform behavior. The use of digital tools to document and archive identifiable information is regularly debated by ethicists and legal scholars and will likely be an important area of scholarship in the coming years.

APPLIED RESEARCH

Applied research is inquiry using the application of scientific methodology with the purpose of generating empirical observations to solve critical problems in society. It is widely used in varying contexts, ranging from applied behavior analysis to city planning and public policy and to program evaluation. Applied research can be executed through a diverse range of research strategies that can be solely quantitative, solely qualitative, or a mixed method research design that combines quantitative and qualitative data slices in the same project. What all the multiple facets in applied research projects share

is one basic commonality—the practice of conducting research in “nonpure” research conditions because data are needed to help solve a real-life problem.

The most common way applied research is understood is by comparing it to *basic research*. Basic research—“pure” science—is grounded in the scientific method and focuses on the production of new knowledge and is not expected to have an immediate practical application. Although the distinctions between the two contexts are arguably somewhat artificial, researchers commonly identify four differences between applied research and basic research. Applied research differs from basic research in terms of purpose, context, validity, and methods (design).

Research Purpose

The purpose of applied research is to increase what is known about a problem with the goal of creating a better solution. This is in contrast to basic research, in which the primary purpose is to expand on what is known—knowledge—with little significant connections to contemporary problems. A simple contrast that shows how research purpose differentiates these two lines of investigation can be seen in applied behavior analysis and psychological research. Applied behavior is a branch of psychology that generates empirical observations that focus at the level of the individual with the goal of developing effective interventions to solve specific problems. Psychology, on the other hand, conducts research to test theories or explain changing trends in certain populations.

The irrelevance of basic research to immediate problems may at times be overstated. In one form or another, observations generated in basic research eventually influence what we know about contemporary problems. Going back to the previous comparison, applied behavior investigators commonly integrate findings generated by cognitive psychologists—how people organize and analyze information—in explaining specific types of behaviors and identifying relevant courses of interventions to modify them. The question is, how much time needs to pass (5 months, 5 years, 50 years) in the practical application of research results in order for the research to be deemed basic research? In general, applied research observations are intended to be implemented in the first few years whereas basic researchers make no attempt to identify when their observations will be realized in everyday life.

Research Context

The point of origin at which a research project begins is commonly seen as the most significant difference

between applied research and basic research. In applied research, the context of pressing issues marks the beginning in a line of investigation. Applied research usually begins when a client has a need for research to help solve a problem. The context the client operates in provides the direction the applied investigator takes in terms of developing the research questions. The client usually takes a commanding role in framing applied research questions. Applied research questions tend to be open ended because the client sees the investigation as being part of a larger context made up of multiple stakeholders who understand the problem from various perspectives.

Basic research begins with a research question that is grounded in theory or previous empirical investigations. The context driving basic research takes one of two paths: testing the accuracy of hypothesized relationships among identified variables or confirming existing knowledge from earlier studies. In both scenarios, the basic research investigator usually initiates the research project based on his or her ability to isolate observable variables and to control and monitor the environment in which they operate. Basic research questions are narrowly defined and are investigated with only one level of analysis: prove or disprove theory or confirm or not confirm earlier research conclusions.

The contrast in the different contexts between applied research and basic research is simply put by Jon S. Bailey and Mary R. Burch in their explanation of applied behavior research in relation to psychology. The contrast can be pictured like this: In applied behavior research, subjects walk in the door with unique family histories that are embedded in distinct communities. In basic research, subjects “come in packing crates from a breeding farm, the measurement equipment is readily available, the experimental protocols are already established, and the research questions are derivative” (p. 3).

Emphasis on Validity

The value of all research—applied and basic—is determined by its ability to address questions of internal and external validity. Questions of *internal validity* ask whether the investigator makes the correct observation on the causal relationship among identified variables. Questions of *external validity* ask whether the investigators appropriately generalize observations from their research project to relevant situations. A recognized distinction is that applied research values external validity more than basic research projects do. Assuming an applied research project adequately addresses questions of internal validity, its research conclusions are more closely assessed in how well they apply directly to solving problems.

Questions of internal validity play a more significant role in basic research. Basic research focuses on capturing, recording, and measuring causal relationships among identified variables. The application of basic research conclusions focuses more on their relevance to theory and the advancement of knowledge than on their generalizability to similar situations.

The difference between transportation planning and transportation engineering is one example of the different validity emphasis in applied research and basic research. Transportation planning is an applied research approach that is concerned with the siting of streets, highways, sidewalks, and public transportation to facilitate the efficient movement of goods and people. Transportation planning research is valued for its ability to answer questions of external validity and address transportation needs and solve traffic problems, such as congestion at a specific intersection. Traffic engineering is the basic research approach to studying function, design, and operation of transportation facilities and looks at the interrelationship of variables that create conditions for the inefficient movement of goods and people. Traffic engineering is valued more for its ability to answer questions of internal validity in correctly identifying the relationship among variables that can cause traffic and makes little attempt to solve specific traffic problems.

Research Design

Applied research projects are more likely follow a *triangulation* research design than are basic research investigations. Triangulation is the research strategy that uses a combination of multiple data sets, multiple investigators, multiple theories, and multiple methodologies to answer research questions. This is largely because of the context that facilitates the need for applied research. Client-driven applied research projects tend to need research that analyzes a problem from multiple perspectives in order to address the many constituents that may be impacted by the study. In addition, if applied research takes place in a less than ideal research environment, multiple data sets may be necessary in order for the applied investigator to generate a critical mass of observations to be able to make defensible conclusions about the problem at hand.

Basic research commonly adheres to a single-method, single-data-research strategy. The narrow focus in basic research requires the investigator to eliminate possible research variability (bias) to better isolate and observe changes in the studied variables. Increasing the number of types of data sets accessed and methods used to obtain them increases the possible risk of contaminating the basic research laboratory of observations.

Research design in transportation planning is much more multifaceted than research design in traffic engineering. This can be seen in how each approach would go about researching transportation for older people. Transportation planners would design a research strategy that would look at the needs of a specific community and assess several different data sets (including talking to the community) obtained through several different research methods to identify the best combination of interventions to achieve a desired outcome. Traffic engineers will develop a singular research protocol that focuses on total population demand in comparison with supply to determine unmet transportation demand of older people.

APTITUDES AND INSTRUCTIONAL METHODS

Research on the interaction between student characteristics and instructional methods is important because it is commonly assumed that different students learn in different ways. That assumption is best studied by investigating the interaction between student characteristics and different instructional methods. The study of that interaction received its greatest impetus with the publication of Lee Cronbach and Richard Snow's *Aptitudes and Instructional Methods* in 1977, which summarized research on the interaction between aptitudes and instructional treatments, subsequently abbreviated as ATI research. Cronbach and Snow indicated that the term *aptitude*, rather than referring exclusively to cognitive constructs, as had previously been the case, was intended to refer to any student characteristic. Cronbach stimulated research in this area in earlier publications suggesting that ATI research was an ideal meeting point between the usually distinct research traditions of correlational and experimental psychology. Before the 1977 publication of *Aptitudes and Instructional Methods*, ATI research was spurred by Cronbach and

Snow's technical report summarizing the results of such studies, which was expanded in 1977 with the publication of the volume.

Background

When asked about the effectiveness of different treatments, educational researchers often respond that "it depends" on the type of student exposed to the treatment, implying that the treatment interacted with some student characteristic. Two types of interactions are important in ATI research: *ordinal* and *disordinal*, as shown in Figure 1. In ordinal interactions (top two lines in Figure 1), one treatment yields superior outcomes at all levels of the student characteristic, though the difference between the outcomes is greater at one part of the distribution than elsewhere. In disordinal interactions (the bottom two lines in Figure 1), one treatment is superior at one point of the student distribution while the other treatment is superior for students falling at another point. The slope difference in ordinal interactions indicates that ultimately they are also likely to be disordinal, that is, the lines will cross at a further point of the student characteristic distribution than observed in the present sample.

Research Design

ATI studies typically provide a segment of instruction by two or more instructional methods that are expected to be optimal for students with different characteristics. Ideally, research findings or some strong theoretical basis should exist that leads to expectations of differential effectiveness of the instruction for students with different characteristics. Assignment to instructional method may be entirely random or random within categories of the student characteristic. For example, students may be randomly assigned to a set of instructional methods and their anxiety then determined by some measure or experimental procedure. Or, in quasi-experimental designs, high- and low-anxiety students may be determined first and then—within the high- and low-anxiety groups—assignment to instructional methods should be random.

ATI research was traditionally analyzed with analysis of variance (ANOVA). The simplest ATI design conforms to a 2×2 ANOVA, with two treatment groups and two groups (high and low) on the student characteristic. In such studies, main effects were not necessarily expected for either the treatment or the student characteristic, but the interaction between them is the result of greatest interest.

Figure 1 Ordinal and Disordinal Interactions

Cronbach and Snow pointed out that in ANOVA designs, the student characteristic examined was usually available as a continuous score that had at least ordinal characteristics, and the research groups were developed by splitting the student characteristic distribution at some point to create groups (high and low; high, medium, and low; etc.). Such division into groups ignored student differences within each group and reduced the available variance by an estimated 34%. Cronbach and Snow recommended that research employ multiple linear regression analysis in which the treatments would be represented by so-called dummy variables and the student characteristic could be analyzed as a continuous score. It should also be noted, however, that when the research sample is at extreme ends of the distribution (e.g., one standard deviation above or below the mean), the use of ANOVA maximizes the possibility of finding differences between the groups.

ATI Research Review

Reviews of ATI research reported few replicated interactions. Among the many reasons for these inconsistent findings were vague descriptions of the instructional treatments and sketchy relationships between the student characteristic and the instruction. Perhaps the most fundamental reason for the inconsistent findings was the inability to identify the cognitive processes required by the instructional treatments and engaged by the student characteristic. Slava Kalyuga, Paul Ayres, Paul Chandler, and John Sweller demonstrated that when the cognitive processes involved in instruction have been clarified, more consistent ATI findings have been reported and replicated.

Later reviews of ATI research, such as those by J. E. Gustaffson and J. O. Undheim or by Sigmund Tobias, reported consistent findings for Tobias's general hypothesis that students with limited knowledge of a domain needed instructional support, that is, assistance to the learner, whereas more knowledgeable students could succeed without it. The greater consistency of interactions involving prior knowledge as the student characteristic may be attributable to some attributes of such knowledge. Unlike other student characteristics, prior domain knowledge contains the cognitive processes to be used in the learning of that material. In addition, the prior knowledge measure is likely to have been obtained in a situation fairly similar to the one present during instruction, thus also contributing any variance attributable to *situativity* to the results.

APTITUDE-TREATMENT INTERACTION

There are countless illustrations in the social sciences of a description of a phenomenon existing for many years before it is labeled and systematized as a scientific concept. One such example is in Book II of Homer's *Iliad*, which presents an interesting account of the influence exerted by Agamemnon, king of Argos and commander of the Greeks in the Trojan War, on his army. In particular, Homer describes the behavior of Odysseus, a legendary king of Ithaca, and the behavior of Thersites, a commoner and rank-and-file soldier, as contrasting responses to Agamemnon's leadership and role as "the shepherd of the people." Odysseus, Homer says, is "brilliant," having "done excellent things by thousands," while he describes Thersites as that "who knew within his head many words, but disorderly," and "this thrower of words, this braggart." Where the former admires the leadership of Agamemnon, accepts his code of honor, and responds to his request to keep the sage of Troy, the latter accuses Agamemnon of greed and promiscuity and demands a return to Sparta.

The observation that an intervention—educational, training, therapeutic, or organizational—when delivered the same way to different people might result in differentiated outcomes, was made a long time ago, as long as the 8th century BCE, as exemplified by Homer. In attempts to comprehend and explain this observation, researchers and practitioners have focused primarily on the concept of individual differences, looking for main effects that are attributable to concepts such as ability, personality, motivation, or attitude. When these inquiries started early in the 20th century, not many parallel interventions were available. In short, the assumption at the time was that a student (a trainee in a workplace, a client in a clinical setting, or a soldier on a battlefield) possessed specific characteristics, such as Charles Spearman's *g* factor of intelligence, that could predict his or her success or failure in a training situation. However, this attempt to explain the success of an intervention by the characteristics of the intervenee was challenged by the appearance of multiple parallel interventions aimed at arriving at the same desired goal by employing various strategies and tactics. It turned out that there were no ubiquitous collections of individual characteristics that would always result in success in a situation. Moreover, as systems of intervention in education, work training in industry, and clinical fields developed, it became apparent that different interventions, although they might be focused on the same target (e.g., teaching children to read, training bank tellers

to operate their stations, helping a client overcome depression, or preparing soldiers for combat), clearly worked differently for different people. It was then suggested that the presence of differential outcomes of the same intervention could be explained by aptitude-treatment interaction (ATI, sometimes also abbreviated as AxT), a concept that was introduced by Lee Cronbach in the second part of the 20th century.

ATI methodology was developed to coaccount both for the individual characteristics of the intervenee and the variations in the interventions while assessing the extent to which alternative forms of interventions might have differential outcomes as a function of the individual characteristics of the person to whom the intervention is being delivered. In other words, investigations of ATI have been designed to determine whether particular treatments can be selected or modified to optimally serve individuals possessing particular characteristics (i.e., ability, personality, motivation). Today, ATI is discussed in three different ways: as a concept, as a method for assessing interactions among person and situation variables, and as a framework for theories of aptitude and treatment.

ATI as a Concept

ATI as a concept refers to both an outcome and a predictor of that outcome. Understanding these facets of ATI requires decomposing the holistic concept into its three components—treatment, aptitude, and the interaction between them. The term *treatment* is used to capture any type of manipulation aimed at changing something. Thus, with regard to ATI, treatment can refer to a specific educational intervention (e.g., the teaching of equivalent fractions) or conceptual pedagogical framework (e.g., Waldorf pedagogy), a particular training (e.g., job-related activity, such as mastering a new piece of equipment at a workplace) or self-teaching (e.g., mastering a new skill such as typing), a clinical manipulation (e.g., a session of massage) or long-term therapy (e.g., psychoanalysis), or inspiring a soldier to fight a particular battle (e.g., issuing an order) or preparing troops to use new strategies of war (e.g., fighting insurgency). *Aptitude* is used to signify any systematic measurable dimension of individual differences (or a combination of such) that is related to a particular treatment outcome. In other words, aptitude does not necessarily mean a level of general cognitive ability or intelligence; it can capture specific personality traits or transient psychological states. The most frequently studied aptitudes of ATI are in the categories of cognition, conation, and affection, but aptitudes are not limited to these three categories. Finally, *interaction*

demarcates the degree to which the results of two or more interventions will differ for people who differ in one or more aptitudes. Of note is that interaction here is defined statistically and that both intervention and aptitude can be captured by qualitative or quantitative variables (observed, measured, self-reported, or derived). Also of note is that, being a statistical concept, ATI behaves just as any statistical interaction does. Most important, it can be detected only when studies are adequately powered. Moreover, it acknowledges and requires the presence of main effects of the aptitude (it has to be a characteristic that matters for a particular outcome, e.g., general cognitive ability rather than shoe size for predicting a response to educational intervention) and the intervention (it has to be an effective treatment that is directly related to an outcome, e.g., teaching a concept rather than just giving students candy). This statistical aspect of ATI is important for differentiating it from what is referred to by the ATI developers and proponents as *transaction*. Transaction signifies the way in which ATI is constructed, the environment and the process in which ATI emerges; in other words, ATI is always a statistical result of a transaction through which a person possessing certain aptitudes experiences a certain treatment. ATI as an outcome identifies combinations of treatments and aptitudes that generate a significant change or a larger change compared with other combinations. ATI as a predictor points to which treatment or treatments are more likely to generate significant or larger change for a particular individual or individuals.

ATI as a Method

ATI as a method permits the use of multiple experimental designs. The very premise of ATI is its capacity to combine correlational approaches (i.e., studies of individual differences) and experimental approaches (i.e., studies of interventional manipulations). Multiple paradigms have been developed to study ATI; many of them have been and continue to be applied in other, non-ATI, areas of interventional research. In classical accounts of ATI, the following designs are typically mentioned. In a *simple standard randomized between-persons design*, the outcome is investigated for persons who score at different levels of a particular aptitude when multiple, distinct interventions are compared. Having registered these differential outcomes, intervention selection is then carried out based on a particular level of aptitude to optimize the outcome. Within this design, often, when ATI is registered, it is helpful to carry out additional studies (e.g., case studies) to investigate the reason for the manifestation of ATI. The

treatment revision design assumes the continuous adjustment of an intervention (or the creation of multiple parallel versions of it) in response to how persons with different levels of aptitude react to each improvement in the intervention (or alternative versions of the intervention). The point here is to optimize the intervention by creating its multiple versions or its multiple stages so that the outcome is optimized at all levels of aptitude. This design has between- and within-person versions, depending on the purposes of the intervention that is being revised (e.g., ensuring that all children can learn equivalent fractions regardless of their level of aptitude or ensuring the success of the therapy regardless of the variability in depressive states of a client across multiple therapy sessions). In the *aptitude growth design*, the target of intervention is the level of aptitude. The idea here is that as the level of aptitude changes, different types of interventions might be used to optimize the outcome. This type of design is often used in combination with growth-curve analyses. It can be applied as either between-persons or within-person designs. Finally, a type of design that has been gaining much popularity lately is the *regression discontinuity design*. In this design, the presence of ATI is registered when the same intervention is administered before and after a particular event (e.g., a change in aptitude in response to linguistic immersion while living in a country while continuing to study the language of that country).

ATI as a Theoretical Framework

ATI as a theoretical framework underscores the flexible and dynamic, rather than fixed and deterministic, nature of the coexistence (or coaction) of individual characteristics (i.e., aptitudes) and situations (i.e., interventions). As a theory, ATI captures the very nature of variation in learning—not everyone learns equally well from the same method of instruction, and not every method of teaching works for everyone; in training—people acquire skills in a variety of ways; in therapy—not everyone responds well to a particular therapeutic approach; and in organizational activities—not everyone prefers the same style of leadership. In this sense, as a theoretical framework, ATI appeals to professionals in multiple domains as it justifies the presence of variation in outcomes in classrooms, work environments, therapeutic settings, and battlefields. While applicable to all types and levels of aptitudes and all kinds of interventions, ATI is particularly aligned with more extreme levels of aptitudes, both low and high, and more specialized interventions. The theory of ATI acknowledges the presence of heterogeneity in both aptitudes and interventions, and its premise is to find

the best possible combinations of the two to maximize the homogeneity of the outcome. A particular appeal of the theory is its transactional nature and its potential to explain and justify both success and failure in obtaining the desired outcome. As a theoretical framework, ATI does not require the interaction to either be registered empirically or be statistically significant. It calls for a theoretical examination of the aptitude and interventional parameters whose interaction would best explain the dynamics of learning, skill acquisition and demonstration, therapy, and leadership. The beneficiaries of this kind of examination are of two kinds. First, it is the researchers themselves. Initially thinking through experiments and field studies before trying to confirm the existence of ATI empirically was, apparently, not a common feature of ATI studies during the height of their popularity. Perhaps a more careful consideration of the “what, how, and why” of measurement in ATI research would have prevented the observation that many ATI findings resulted from somewhat haphazard fishing expeditions, and the resulting views on ATI research would have been different. A second group of beneficiaries of ATI studies are practitioners and policy makers. That there is no intervention that works for all, and that one has to anticipate both successes and failures and consider who will and who will not benefit from a particular intervention, are important realizations to make while adopting a particular educational program, training package, therapeutic approach, or organizational strategy, rather than in the aftermath. However, the warning against embracing panaceas, made by Richard Snow, in interventional research and practice is still just a warning, not a common presupposition.

Criticism

Having emerged in the 1950s, interest in ATI peaked in the 1970s and 1980s, but then dissipated. This expansion and contraction were driven by an initial surge in enthusiasm, followed by a wave of skepticism about the validity of ATI. Specifically, a large-scope search for ATI, whose presence was interpreted as being marked by differentiated regression slopes predicting outcomes from aptitudes for different interventions, or by the significance of the interaction terms in analysis of variance models, was enthusiastically carried out by a number of researchers. The accumulated data, however, were mixed and often contradictory—there were traces of ATI, but its presence and magnitude were not consistently identifiable or replicable. Many reasons have been mentioned in discussions of why ATI is so elusive: underpowered studies, weak theoretical conceptualizations of ATI, simplistic research designs, imperfections

in statistical analyses, and the magnitude and even the nonexistence of ATI, among others. As a result of this discussion, the initial prediction of the originator of ATI's concept, Lee Cronbach, that interventions designed for the average individual would be ultimately replaced by multiple parallel interventions to fit groups of individuals, was revised. The "new view" of ATI, put forward by Cronbach in 1975, acknowledged that, although in existence, ATI is much more complex and fluid than initially predicted and ATI's dynamism and fluidity prevent professionals from cataloging specific types of ATI and generalizing guidelines for prescribing different interventions to people, given their aptitudes. Although the usefulness of ATI as a theory has been recognized, its features as a concept and as a method have been criticized along the lines of (a) our necessarily incomplete knowledge of all possible aptitudes and their levels, (b) the shortage of good psychometric instruments that can validly and reliably quantify aptitudes, (c) the biases inherent in many procedures related to aptitude assessment and intervention delivery, and (d) the lack of understanding and possible registering of important "other" nonstatistical interactions (e.g., between student and teacher, client and therapist, environment and intervention). And yet ATI has never been completely driven from the field, and there have been steady references to the importance of ATI's framework and the need for better-designed empirical studies of ATI.

Gene $\times$ Environment Interaction

ATI has a number of neighboring concepts that also work within the general realm of qualifying and quantifying individual differences in situations of acquiring new knowledge or new skills. Among these concepts are learning styles, learning strategies, learning attitudes, and many interactive effects (e.g., aptitude-outcome interaction). Quite often, the concept of ATI is discussed side by side with these neighboring concepts. Of particular interest is the link between the concept of ATI and the concept of Gene $\times$ Environment interaction ($G \times E$). The concept of $G \times E$ first appeared in nonhuman research but gained tremendous popularity in the psychological literature within the same decade. Of note is that the tradition of its use in this literature is very similar to that of the usage of ATI; specifically, $G \times E$ also can be viewed as a concept, a method, and a theoretical framework. But the congruence between the two concepts is incomplete, of course; the concept of $G \times E$ adopts a very narrow definition of aptitude, in which individual differences are reduced to genetic variation, and a very broad

definition of treatment, in which interventions can be equated with live events. Yet an appraisal of the parallels between the concepts of ATI and $G \times E$ is useful because it captures the field's desire to engage interaction effects for explanatory purposes whenever the explicatory power of main effects is disappointing. And it is interesting that the accumulation of the literature on $G \times E$ results in a set of concerns similar to those that interrupted the golden rush of ATI studies in the 1970s.

Yet methodological concerns aside, the concept of ATI rings a bell for all of us who have ever tried to learn anything in a group of people: what works for some of us will not work for the others as long as we differ on even one characteristic that is relevant to the outcome of interest. Whether it was wit or something else by which Homer attempted to differentiate Odysseus and Thersites, the poet did at least successfully make an observation that has been central to many fields of social studies and that has inspired the appearance of the concept, methodology, and theoretical framework of ATI, as well as the many other concepts that capture the essence of what it means to be an individual in any given situation: that individual differences in response to a common intervention exist. Millennia later, it is an observation that still claims our attention.

ARGUMENT-BASED APPROACH TO VALIDITY

Assessments (measures and tests) are used to assign values to attributes of people (or groups of people or objects). The assessment typically involves a limited sample of the person’s behavior collected under standardized conditions, while the attribute of interest is defined much more broadly. The need for validation arises from this gap between the observed assessment results (i.e., a score) and the more general claims associated with the attribute being assessed (e.g., level of reading achievement). Validation examines how well the claims based on the assessment scores are justified.

Rather than defining validity as an abstract property of an assessment, the argument-based approach treats validation as an evaluation of the plausibility of the interpretation and uses proposed for the assessment scores. It employs two kinds of arguments in doing so. The *interpretation/use argument (IUA)* specifies a chain or network of inferences and supporting assumptions leading from the assessment results to the proposed interpretation and use. The *validity argument* evaluates the plausibility of the IUA in terms of its completeness (how well it represents the proposed interpretation and use), its coherence (how well it hangs together), and the plausibility of its inferences and assumptions. This entry further describes the argument-based approach to validity and discusses its historical antecedents, the roles of the IUA and the validity argument, and the use of inferences, arguments, and supporting evidence. It then looks at the development of the IUA, assessment, and validity argument and determination of the necessary and sufficient conditions for validity.

The argument-based approach is very general in that it is applicable to any interpretation or use of assessment scores, but it is contingent in that the

evidence required for validation depends on the claims being made. Once the interpretation and use are specified as an IUA, the requirements for validation can be specified. That is, the IUA provides a framework for validating the proposed score interpretations and uses.

The validity argument subjects the IUA to challenges by questioning its assumptions and, where appropriate, by subjecting specific assumptions to empirical checks. Validation is never final or absolute because any of the claims being made can be overturned by new evidence, but an IUA that survives all reasonable challenges can be accepted as valid and used to support score-based claims about individuals or groups in the population. An exception to a standard interpretation or score use may be claimed on the basis of unusual circumstances (e.g., for a person with a disability), but in general, if the IUA represents the proposed interpretation and uses accurately, and its inferences and assumptions are supported by appropriate evidence, it can be considered valid.

Historical Antecedents

Validity analyses have been applied to a wide range of possible score interpretations and uses, and many different kinds of evidence and analyses have been employed in evaluating the claims being made. In the early 20th century, psychological assessments were evaluated in terms of how well they reflected the attribute of interest (e.g., intelligence) and in terms of the consistency of scores across replications of the assessment on the same people. Consistency across replications was evaluated under the heading of *reliability*, and the appropriateness of the interpretation was evaluated under the heading of *validity*. As new types of educational achievement tests (e.g., objective tests) were introduced early in the 20th century, they were evaluated in terms of how well their content matched the content of instruction and in terms of their reliability. These evaluations are generally considered under the heading of *content validity*.

By the 1920s, test scores were also being used to predict outcomes, or criteria, of interest (e.g., success on a job) as a basis for selection and placement decisions. These predictive uses of assessments were evaluated by developing a criterion measure of the desired outcome and investigating how well the assessment scores predicted the criterion. This type of evaluation was considered under the heading of *predictive validity* or *criterion validity*.

In the early 1950s, Lee Cronbach and Paul Meehl borrowed the notion of a theoretical construct defined in terms of its role in a theory from then-current models in the philosophy of science. In their construct-validity

model, the construct was defined implicitly in terms of its role in a theory, and the theory and the construct interpretation were evaluated together by examining whether the relationships implied by the theory were satisfied when the construct was estimated by assessment scores. If the theory implied that certain relationships should exist between the construct of interest and other variables, and these relationships were confirmed when the assessment scores were used to estimate the construct, both the theory and the construct interpretation of the scores would be supported. If some of the anticipated relationships were not confirmed, doubt would be cast on either the theory or the interpretation of the assessment scores. The construct validity model was quite elegant, but it was hard to apply in practice because it required a well-established theory to define the construct, and such theories were not generally available.

By the 1970s, a number of distinct validity models, including the criterion, content, and construct models (plus many more specific models), were in widespread use, generating considerable conceptual and practical ambiguity about what was required for adequate validation. In response, Samuel Messick developed a unified model of validity based on a generalized version of the construct model. Messick's model emphasized the need for multiple lines of evidence for the proposed construct interpretation and the need to evaluate the consequence of assessment uses. Like the original version of the construct model, Messick's unified construct-based model was hard to apply.

In the late 1980s and 1990s, Cronbach, Michael Kane, Lorrie Shepard, and Lyle Bachman proposed argument-based approaches as a more practical framework for validity. Rather than defining validity in terms of theory-based construct interpretations, these argument-based approaches focused on the specific inferences and assumptions inherent in the proposed interpretations and uses of the scores.

IUA and Validity Argument

As noted earlier, the argument-based approach to validity employs two kinds of arguments. The IUA specifies the inferences and assumptions inherent in the proposed interpretations and uses of the scores, and the validity argument evaluates the IUA in terms of its overall plausibility. The IUA lays out the interpretations and uses of the scores as a network of inferences and decisions and makes a preliminary case for their plausibility. The IUA plays the role that a scientific theory plays in the original construct model proposed by Cronbach and Meehl, but it allows for a wide range of possible interpretations ranging from simple generalizations

of the assessment observations (e.g., in a performance test) to ambitious theoretical interpretations, as well as a range of intended uses of the scores. The more complex and ambitious score interpretations and uses generally involve more inferences and assumptions than the simpler interpretations.

The validity argument evaluates the claims in the IUA. The proposed interpretations and uses are considered valid to the extent that the IUA accurately represents the claims based on the scores and that its assumptions are adequately supported by appropriate evidence. Different interpretations and uses will rely on different inferences and assumptions and, therefore, will require different kinds of evidence for their evaluation. More complex IUAs will usually require more evidence than less complex IUAs.

Inferences, Assumptions, and Supporting Evidence

The structure and content of the validity argument will vary from case to case depending on the structure and content of the IUA. If the IUA involves only a few inferences and assumptions, the validity argument might rely on a few types of evidence (i.e., the evidence needed to evaluate the inferences and assumptions in the IUA), and if these inferences and assumptions are highly plausible a priori, the IUA might not require much empirical support for its validation. On the other hand, if the IUA includes a number of questionable assumptions, its evaluation might require an extensive body of empirical evidence.

A *scoring inference* assigns a score to each person's responses to the tasks included in the assessment and combines these task scores into an observed score for the person. The scoring rule would typically be based on the judgment of experts who develop and review the scoring criteria. If the assessment performances are evaluated by raters who apply the scoring criteria to each performance, analyses of the accuracy and consistency with which the scoring rule is applied (e.g., interrater reliability studies) would generally be expected. If the scoring procedures rely on statistical models (e.g., for scaling), the assumptions built into these models would be examined.

A *generalization inference* extends the interpretation from the person's observed score, based on a limited sample of observations, to the expected score over repeated assessments involving different, allowable conditions of observation (e.g., different occasions or raters). The generalization inference does not change the value of the score, but it does broaden its interpretation. Generalization from results on a particular application of the assessment to the expected value

over repeated application of the assessment under comparable conditions is a statistical inference that relies on evidence that the sampling is representative of the universe and that the sample size is large enough to ensure that the sampling error is minimal. Empirical analyses of this inference are generally discussed under the headings of reliability or generalizability theory. The IUA should indicate the range of conditions of observation (e.g., items, contexts, occasions, raters) over which the score is expected to be relatively invariant.

An *extrapolation inference* extends the interpretation to the larger domain of observations associated with the attribute of interest. Assessments are generally standardized in various ways to promote fairness and reliability. The standardized observations are drawn from a relatively narrow slice of the behavioral domain associated with the attribute and, therefore, are not representative of the attribute. Extending the interpretation to the much larger and less well-defined domain associated with the attribute generally relies on analyses that indicate that the tasks in the assessment depend on skills or propensities that are central to the conception of the attribute.

It may also be possible to empirically examine the relationships between the assessment scores and more direct measures of the attribute. For example, scores on a multiple-choice test of English composition skills might be compared to ratings of essays written by the same students. If the assessment is representative of the attribute of interest (e.g., using an essay test to assess skill in writing essays), the extrapolation would not require much support, but if the assessment is substantially different from the attribute (e.g., using a multiple-choice test to assess writing), it is important to rule out the possibility that the scores are overly dependent on the assessment format.

Predictive inferences use assessment scores to predict future behavior in some context (e.g., in an instructional program). These inferences tend to rely mainly on statistical evidence that there is a positive relationship between a person's assessment score and their standing on some criterion measure (e.g., college GPA).

Theory-based inferences rely on a theory, indicating that certain relationships should hold. For example, in Cronbach and Meehl's original version of the construct model, the constructs were assumed to be embedded in theoretical networks that could provide support for various inferences. If the theory's implications are consistent with observations based on the assessment, the theory and the interpretations of the assessment scores in terms of the theory are both supported. In particular, if the theory suggests that the construct should be related to another variable in a particular way, the

assessment scores should relate to that variable in that way. If the theory implies that the construct should be largely independent of another variable, the assessment scores should be independent of that variable.

Inferences from score interpretation to score-based decisions generally involve claims that these decisions will lead to positive outcomes and will avoid negative consequences in most cases. Decisions that achieve their intended goals without serious side effects are considered acceptable, and those that do not achieve their intended goals or have serious side effects are not acceptable. A testing program with some negative consequences may be considered acceptable if it achieves its intended outcomes, but a program with serious negative consequences is not likely to be accepted.

In evaluating assessment programs, improvements in intended outcomes, like worker productivity, are important, but fairness to individuals and groups (e.g., racial-ethnic groups, language groups, genders) is equally important. Note that negative consequences always count against the decision, but they do not necessarily count against the underlying interpretation unless they indicate some defect in the underlying interpretation. The fact that an arithmetic test is not useful in predicting success in medical school does not count against its validity as a measure of arithmetic.

With the argument-based approach, validation requires the specification of the inferences and assumptions inherent in the proposed interpretation and use of the scores and then the evaluation of these inferences and assumptions in a validity argument. Because the claims vary from one interpretation/use to another, the evidence required for validation depends on the claims being made. To support the proposed interpretations and uses, the validity argument needs to justify the IUA as a whole and to rule out plausible alternative interpretations. In this process, the most doubtful parts of the argument deserve the most scrutiny because the intended interpretation or use can be undermined by a failure of any part of the IUA, even if the rest of the argument is highly plausible.

Developing the IUA, Assessment, and Validity Argument

In the early stages of assessment development, the goal is to outline a plausible IUA and an assessment that work together to support the proposed interpretation and use of the scores. Early on, any weaknesses that are identified in the IUA or the assessment tend to be addressed by adjusting the assessment or the IUA or both, but at some point the focus should shift to a more critical stance. Before the assessment is used operationally, the proposed

IUA should be subjected to critical review, with a particular focus on subjecting its most questionable assumptions to empirical challenges.

The requirement that the inferences and assumptions be explicitly stated and evaluated in the IUA provides some protection against inappropriate interpretations and uses of the resulting scores. To the extent that the IUA is clearly stated, gaps and inconsistencies are harder to ignore. However, just as we don't want to omit inferences or assumptions that should be in the IUA, we don't want to include inferences or assumptions that are not necessary; doing so could lead to a false-negative conclusion about validity. A proposed interpretation or use that has undergone a critical evaluation of its coherence and of the plausibility of its inferences and assumptions can be provisionally accepted as being valid, with the understanding that new evidence could lead to a reconsideration of this conclusion.

Necessary and Sufficient Conditions for Validity

The argument-based approach to validation does not specify any particular kind of interpretation or use for scores, but it does require that the claims based on the scores be clearly stated and adequately supported. More ambitious interpretations require more support, but a clear specification of the proposed interpretation and use also puts limits on the evidence required for validation. If neither the interpretation nor use requires a particular inference or assumption, there is no need to investigate that inference or assumption. For example, essentially all score interpretations require generalizability over some conditions of observation (e.g., over raters, or items, or occasions); if the scores did not generalize at all, they would simply be summaries of the observed responses. However, if the attribute being assessed (e.g., mood) is not assumed to be invariant over occasions, there would be no reason to require that the assessment scores be generalizable over occasions. Hence, adequate generalizability, or reliability, over a particular kind of condition of observation is necessary for validity if and only if the interpretation or use of the scores requires generalization over that kind of condition. The IUA specifies necessary and sufficient conditions for accepting the proposed score interpretations and uses as valid.

The extent to which the IUA fully represents the proposed interpretation and use of the scores is always questionable, and the adequacy of the evidence for various inferences and assumptions in the IUA is subject to debate. Nevertheless, if the IUA accurately reflects the intended interpretations and uses of the scores, and the validity argument supports the IUA, the

proposed interpretation and use can be considered valid, at least for the time being. The criteria for accepting the validity of a proposed interpretation and use are essentially the same as the criteria for accepting a scientific theory. In both cases, we never achieve certainty, but with reasonable effort, we can achieve a high degree of confidence in the theory or in the interpretations and uses.

Concluding Remarks

The evidence required for argument-based validation depends on the proposed interpretation and use of the scores. Score interpretations that make very modest claims (e.g., claims about the level of skill in the activities included in the assessment) do not require much evidence for validation. Ambitious interpretations and uses can require an extended research program for their validation. If the IUA is coherent and complete, and all of its inferences and assumptions are supported by appropriate evidence, the proposed interpretations and uses can be considered valid. If the IUA is incomplete, or some of its inferences or assumptions are not plausible, some parts of the proposed interpretation and/or some proposed uses would be rejected.

A failure to specify the proposed interpretations and uses clearly and in some detail makes it difficult to develop a fully adequate validation effort because implicit inferences and assumptions could be overlooked. An IUA that understates the intended interpretation and use begs at least some questions, and as a result, the validation effort will not adequately evaluate the actual interpretation and use. An IUA that overstates the interpretation and use (by including some inferences or assumptions that are not required for the actual interpretation and use) will make validation more difficult and may lead to an erroneous conclusion that the scores are not valid for the interpretation and use.

The goal is to evaluate the plausibility of the claims being based on the assessment scores. Validation may not be easy, but it is generally possible to do a reasonably good job of validation with a manageable level of effort.

ASSENT

The term *assent* refers to the verbal or written agreement to engage in a research study. Assent is generally applicable to children between the ages of 8 and 18 years, although assent may apply to other vulnerable populations also.

Vulnerable populations are those composed of individuals who are unable to give consent due to diminished autonomy. Diminished autonomy occurs when an individual is incapacitated, has restricted freedom, or is a minor. Understanding the relevance of assent is important because without obtaining the assent of a participant, the researcher has restricted the freedom and autonomy of the participant and in turn has violated the basic ethical principle of respect for persons. Assent with regard to vulnerable populations is discussed here, along with the process of obtaining assent and the role of institutional review boards in the assent process.

Vulnerable Populations

Respect for persons requires that participants agree to engage in research voluntarily and have adequate information to make an informed decision. Most laws recognize that a person 18 years of age or older is able to give his or her informed *consent* to participate in the research study. However, in some cases individuals lack the capacity to provide informed consent. An individual may lack the capacity to give his or her consent for a variety of reasons; examples include a prisoner who is ordered to undergo an experimental treatment designed to decrease recidivism, a participant with an intellectual developmental disorder or an older adult with dementia whose caretakers believe an experimental psychotherapy group may decrease his or her symptoms. Each of the participants in these examples is not capable of giving permission to participate in the research because he or she either is coerced into engaging in the research

or lacks the ability to understand the basic information necessary to fully consent to the study.

State laws prohibit minors and incapacitated individuals from giving consent. In these cases, permission must be obtained from parents and court-appointed guardians, respectively. However, beyond consent, many ethicists, professional organizations, and ethical codes require that *assent* be obtained. With children, state laws define when a young person is legally competent to make informed decisions. Some argue that the ability to give assent is from 8 to 14 years of age because the person is able to comprehend the requirements of the research. In general, however, it is thought that by the age of 10, children should be able to provide assent to participate. It is argued that obtaining assent increases the autonomy of the individual. By obtaining assent, individuals are afforded as much control as possible over their decision to engage in the research given the circumstances, regardless of their mental capacity.

Obtaining Assent

Assent is not a singular event. It is thought that assent is a continual process. Thus, researchers are encouraged to obtain permission to continue with the research during each new phase of research (e.g., moving from one type of task to the next). If an individual assents to participate in the study but during the study requests to discontinue, it is recommended that the research be discontinued.

Although obtaining assent is strongly recommended, failure to obtain assent does not necessarily preclude the participant from engaging in the research. For example, if the parent of a 4-year-old child gives permission for the child to attend a social skills group for socially anxious children, but the child does not assent to treatment, the child may be enrolled in the group without his or her assent. However, it is recommended that assent be obtained whenever possible. Further, if a child does not give assent initially, attempts to obtain assent should continue throughout the research. Guidelines also suggest that assent may be overlooked in cases in which the possible benefits of the research outweigh the costs. For example, if one wanted to study the effects of a lifesaving drug for children and the child refused the medication, the benefit of saving the child's life outweighs the cost of not obtaining assent. Assent may be overlooked in cases in which assent of the participants is not feasible, as would be the case of a researcher interested in studying children who died as a result of not wearing a seatbelt.

Obtaining assent is an active process whereby the participant and the researcher discuss the requirements of the research. In this case, the participant is active in

the decision making. *Passive consent*, a concept closely associated with assent and consent, is the lack of protest, objection, or opting out of the research study and is considered permission to continue with the research.

Institutional Review Boards

Institutional review boards frequently make requirements as to the way assent is to be obtained and documented. Assent may be obtained either orally or in writing and should always be documented. In obtaining assent, the researcher provides the same information as is provided to an individual from whom consent is requested. The language level and details may be altered in order to meet the understanding of the assenting participant. Specifically, the participant should be informed of the purpose of the study; the time necessary to complete the study; as well as the risks, benefits, and alternatives to the study or treatment. Participants should also have access to the researcher's contact information. Finally, limits of confidentiality should be addressed. This is particularly important for individuals in the prison system and for children.

ASSOCIATION, MEASURES OF

Measuring association between variables is very relevant for investigating *causality*, which is, in turn, the sine qua non of scientific research. However, an association between two variables does not necessarily imply a causal relationship, and the research design of a study aimed at investigating an association needs to

be carefully considered in order for the study to obtain valid information. Knowledge of measures of association and the related ideas of *correlation*, *regression*, and *causality* are cornerstone concepts in research design. This entry is directed at researchers disposed to approach these concepts in a conceptual way.

Measuring Association

In scientific research, association is generally defined as the statistical dependence between two or more variables. Two variables are associated if some of the variability of one variable can be accounted for by the other, that is, if a change in the quantity of one variable conditions a change in the other variable.

Before investigating and measuring association, it is first appropriate to identify the types of variables that are being compared (e.g., nominal, ordinal, discrete, continuous). The type of variable will determine the appropriate statistical technique or test that is needed to establish the existence of an association. If the statistical test shows a conclusive association that is unlikely to occur by random chance, different types of regression models can be used to quantify how change in *exposure* to a variable relates to the change in the *outcome* variable of interest.

Examining Association Between Continuous Variables With Correlation Analyses

Correlation is a measure of association between two variables that expresses the degree to which the two variables are rectilinearly related. If the data do not follow a straight line (e.g., they follow a curve), common correlation analyses are not appropriate. In correlation, unlike regression analysis, there are no dependent and independent variables.

When both variables are measured as discrete or continuous variables, it is common for researchers to examine the data for a correlation between these variables by using the *Pearson product-moment correlation coefficient* (r). This coefficient has a value between -1 and $+1$ and indicates the strength of the association between the two variables. A *perfect* correlation of ± 1 occurs only when all pairs of values (or *points*) fall exactly on a straight line.

A positive correlation indicates in a broad way that increasing values of one variable correspond to increasing values in the other variable. A negative correlation indicates that increasing values in one variable corresponds to decreasing values in the other variable. A correlation value close to 0 means no association between the variables. The r provides information about the strength of the correlation (i.e., the nearness

Figure 1 Scatterplots for Correlations of Various Magnitudes

Notes: Simulation examples show perfect positive (a, c) and negative (b) correlations, as well as regression lines with similar correlation coefficients but different slopes (a, c). The figure also shows regression lines with similar slopes but different correlation coefficients (d, e and f, g).

of the points to a straight line). Figure 1 gives some examples of correlations, correlation coefficients, and related regression lines.

A condition for estimating correlations is that both variables must be obtained by random sampling from the same population. For example, one can study the correlation between height and weight in a sample of children but not the correlation between height and three different types of diet that have been decided by the investigator. In the latter case, it would be more appropriate to apply a regression analysis.

The Pearson correlation coefficient may not be appropriate if there are outliers (i.e., extreme values). Therefore, the first step when one is studying correlations is to draw a scatterplot of the two variables to examine whether there are any outliers. These variables should be standardized to the same scale before they are plotted.

If outliers are present, *nonparametric types of correlation coefficients* can be calculated to examine the linear association. The *Spearman rank correlation coefficient*, for example, calculates correlation coefficients

based on the ranks of both variables. *Kendall's coefficient of concordance* calculates the concordance and discordance of the observed (or ranked) exposure and outcome variables between pairs of individuals.

When the variables one is investigating are nominal or have few categories or when the scatterplot of the variables suggests an association that is not rectilinear but, for example, quadratic or cubic, then the correlation coefficients described above are not suitable. In these cases other approaches are needed to investigate the association between variables.

Chi-Square Tests of Association for Categorical Variables

A common method for investigating "general" association between two categorical variables is to perform a *chi-square test*. This method compares the observed number of individuals within cells of a cross-tabulation of the categorical variables with the number of individuals one would expect in the cells if there was no association and the individuals were randomly distributed. If the observed and expected frequencies differ statistically (beyond random chance according to the chi-square distribution), the variables are said to be associated.

A chi-square *test for trend* can also examine for linear association when the exposure category is ordinal. Other statistical tests of association include measurements of agreement in the association, such as the kappa statistic or McNemar's test, which are suitable when the study design is a matched case-control.

Quantifying Association in General and by Regression Analyses in Particular

In *descriptive* research, the occurrence of an outcome variable is typically expressed by group measurements such as averages, proportions, incidence, or prevalence rates. In *analytical* research, an association can be quantified by comparing, for example, the absolute risk of the outcome in the exposed group and in the nonexposed group. Measurements of association can then be expressed either as *differences* (difference in risk) or as *ratios*, such as relative risks (a ratio of risks) or odds ratios (a ratio of odds), and so forth. A ratio with a numerical value greater than 1 (greater than 0 for differences) indicates a positive association between the exposure variable and the outcome variables, whereas a value less than 1 (less than 0 for differences) indicates a negative association. These measures of association can be calculated from cross-tabulation of the outcome variable and exposure categories, or they can be estimated in regression models.

General measures of association such as correlation coefficients and chi-square tests are rather unspecific and provide information only on the existence and strength of an association. *Regression analysis*, however, attempts to model the relationship between two variables by fitting a linear equation to observed data in order to quantify, and thereby predict, the change in the outcome of interest with a unit increase in the exposure variable. In regression analysis, one variable is considered to be an *explanatory variable* (the exposure), and the other is considered to be a *dependent variable* (the outcome).

The method of least squares is the method applied most frequently for fitting a regression line. This method calculates the best-fitting line for the observed data by minimizing the sum of the squares of the vertical deviations from each data point to the line. When a point is placed exactly on the fitted line, its vertical deviation is 0. Deviations are also known as *residuals* or *errors*. The better an explanatory variable predicts the outcome, the lower is the sum of the squared residuals (i.e., residual variance).

A simple *linear regression model*, for example, can examine the increase in blood pressure with a unit increase in age with the regression model

$$Y = a + bX + e,$$

where X is the explanatory variable (i.e., age in years) and Y is the dependent variable (i.e., blood pressure in mm Hg). The slope of the line is b and represents the change in blood pressure for every year of age. Observe that b does not provide information about the strength of the association but only on the average change in Y when X increases by one unit. The strength of the association is indicated by the correlation coefficient r , which informs on the closeness of the points to the regression line (see Figure 1). The parameter a is the intercept (the value of y when $x = 0$), which corresponds to the mean blood pressure in the sample. Finally, e is the residual or error.

A useful measure is the square of the correlation coefficient, r^2 , also called the *coefficient of determination*, and it indicates how much of the variance in the outcome (e.g., blood pressure) is explained by the exposure (e.g., age). As shown in Figure 1, different b s can be found with similar r s, and similar b s can be observed with different r s. For example, many biological variables have been proposed as risk factors for cardiovascular diseases because they showed a high b value, but they have been rejected as common risk factors because their r^2 was very low.

Different types of regression techniques are suitable for different outcome variables. For example, a *logistic regression* is suitable when the outcome is binary (i.e., 0 or 1), and logistic regression can examine, for example, the increased probability (more properly, the increase in log odds) of myocardial infarction with unit increase in age. The *multinomial regression* can be used for analyzing outcome with several categories. A *Poisson regression* can examine how rate of disease changes with exposure, and a *Cox regression* is suitable for survival analysis.

Association Versus Causality

Exposure variables that show a statistical relationship with an outcome variable are said to be *associated* with the outcome. It is only when there is strong evidence that this association is causal that the exposure variable is said to *determine* the outcome. In everyday scientific work, researchers apply a pragmatic rather than a philosophical framework to identify causality. For example, researchers want to discover modifiable causes of a disease.

Statistical associations say nothing by themselves on causality. Their causal value depends on the knowledge background of the investigator and the research design in which these statistical associations are observed. In fact, the only way to be completely sure that an association is causal would be to observe the very same individual living two parallel and exactly similar lives except that in one life, the individual was exposed to the variable of interest, and in the other life, the same individual was not exposed to the variable of interest (a situation called *counterfactual*). In this *ideal design*, the two (hypothetical) parallel lives of the individual are exchangeable in every way except for the exposure itself.

While the ideal research design is just a chimera, there are alternative approaches that try to approximate the ideal design by comparing similar groups of people rather than the same individual. One can, for example, perform an experiment by taking random samples from the same population and randomly allocating the exposure of interest to the samples (i.e., *randomized trials*). In a randomized trial, an association between the average level of exposure and the outcome is possibly causal. In fact, random samples from the same population are—with some random uncertainty—identical concerning both *measured* and *unmeasured* variables, and the random allocation of the exposure creates a counterfactual situation very appropriate for investigating causal associations. The randomized trial design is theoretically closest to the ideal design, but sometimes it is unattainable or unethical to apply this design in the real world.

If conducting a randomized trial is not possible, one can use *observational* designs in order to simulate the ideal design, at least with regard to measured variables. Among observational approaches it is common to use *stratification*, *restriction*, and *multiple regression* techniques. One can also take into account the propensity for exposure when comparing individuals or groups (e.g., *propensity scores techniques*), or one may investigate the same individual at two different times (*case crossover design*). On some occasions one may have access to *natural experiments* or *instrumental variables*.

When planning a research design, it is always preferable to perform a *prospective* study because it identifies the exposure before any individual has developed the outcome. If one observes an association in a *cross-sectional* design, one can never be sure of the direction of the association. For example, low income is associated with impaired health in cross-sectional studies, but it is not known whether bad health leads to low income or the opposite. As noted by Austin Bradford Hill, the existence of a *temporal relationship* is the main criterion for distinguishing causality from association. Other relevant criteria pointed out by this author are *consistency*, *strength*, *specificity*, *dose-response relationship*, *biological plausibility*, and *coherence*.

Bias and Random Error in Association Studies

When planning a study design for investigating causal associations, one needs to consider the possible existence of *random error*, *selection bias*, *information bias*, and *confounding*, as well as the presence of *interactions* or *effect modification* and of *mediator* variables.

Bias is often defined as the lack of *internal validity* of the association between exposure and outcome variable of interest. This is in contrast to *external validity*, which concerns generalizability of the association to other populations. Bias can also be defined as nonrandom or *systematic* difference between an estimate and the true value of the population.

Random Error

When designing a study, one always needs to include a sufficient number of individuals in the analyses to achieve appropriate *statistical power* and ensure that *conclusive estimates* of association can be obtained. Suitable statistical power is especially relevant when it comes to establishing the *absence* of association between two variables. Moreover, when a study involves a large number of individuals, more information is available. More information lowers the random error, which in turn increases the *precision* of the estimates.

Selection Bias

Selection bias can occur if the sample differs from the rest of the population and if the observed association is *modified* by a third variable. The study sample may be different from the rest of the population (e.g., only men or only healthy people), but this situation does not necessarily convey that the results obtained are biased and cannot be applied to the general population. Many randomized clinical trials are performed on a restricted sample of individuals, but the results are actually generalizable to the whole population. However, if there is an *interaction* between variables, the *effect modification* that this interaction produces must be considered. For example, the association between exposure to asbestos and lung cancer is much more intense among smokers than among nonsmokers. Therefore, a study on a population of nonsmokers would not be generalizable to the general population. Failure to consider interactions may even render associations spurious in a sample that includes the whole population. For example, a drug may increase the risk of death in a group of patients but decrease this risk in other different groups of patients. However, an overall measure would show no association since the antagonistic directions of the underlying associations compensate each other.

Information Bias

Information bias simply arises because information collected on the variables is erroneous. All variables must be measured correctly; otherwise, one can arrive at imprecise or even spurious associations.

Confounding

An association between two variables can be confounded by a third variable. Imagine, for example, that one observes an association between the existence of yellow nails and mortality. The causality of this association could be plausible. Since nail tissue stores body substances, the yellow coloration might indicate poisoning or metabolic disease that causes an increased mortality. However, further investigation would indicate that individuals with yellow nails were actually heavy smokers. The habit of holding the cigarette between the fingers discolored their nails, but the cause of death was smoking. That is, smoking was associated with both yellow nails and mortality and originated a confounded association (Figure 2).

Mediation

In some cases an observed association is mediated by an *intermediate* variable. For example, individuals

Figure 2 Deceptive Correlation Between Yellow Nails and Mortality

Note: Because smoking is associated with both yellow nails and mortality, it originated a confounded association between yellow nails and mortality.

Figure 3 Smoking Acts as a Mediator Between Income and Early Death

Note: Heavy smoking mediated the effect of low income on mortality.

with low income present a higher risk of early death than do individuals with high income. Simultaneously, there are many more heavy smokers among people with low income. In this case, heavy smoking mediates the effect of low income on mortality.

Distinguishing which variables are confounders and which are mediators cannot be done by statistical techniques only. It requires previous knowledge, and in some cases variables can be both confounders and mediators.

Directed Acyclic Graphs

Determining which variables are confounders, intermediates, or independently associated variables can be difficult when many variables are involved. Directed acyclic graphs use a set of simple rules to create a visual representation of direct and indirect associations of covariates and exposure variables with the outcome. These graphs can help researchers understand possible causal relationships.

AUDITING

The term “auditing” refers to a systematic review of processes involved in decisions or actions. Typically this is done to ensure conformation with accepted standards or to validate the accuracy of results. In qualitative research, auditing serves a comparable purpose and can be a valuable means of demonstrating the rigor of an investigation. Such a review offers a strong defense against criticisms that are sometimes posed in regard to qualitative research, such as questions regarding the researcher’s neutrality. Auditing of the study, therefore, is a useful means of supporting the credibility and trustworthiness of findings and interpretations in qualitative research.

There continues to be debate over the most appropriate ways to demonstrate credibility or rigor in a qualitative study. Auditing is not an essential part of the process of qualitative research. It can, however, be a useful mechanism to address quality aspects of a study. Many variations of auditing are available for qualitative researchers to apply in their projects. It is important that

plans for an audit are addressed early in the design of a project so that the process can be incorporated in the manner that is most appropriate to each study. This entry describes the ways in which auditing can be conducted in qualitative research, including both internal and external audits and the timing of the auditing process. It also reviews the materials needed for an audit trail.

Methods of Auditing in Qualitative Research

Auditing of a qualitative study involves oversight and, at minimum, review of the conduct of the study and the conclusions developed by investigators. There are numerous ways in which an audit can be carried out in a qualitative study. Variations include who serves as auditor, when the auditing process is initiated, how often auditing occurs, and the extent of the actual audit.

Internal Auditing

Auditing can be conducted on an internal basis in which members of the research team provide a system of checks and balances for each other. This process can promote consistency in the research process and can serve to identify, and subsequently decrease, the bias of any particular team members involved in the research. An internal audit can involve an exchange of documentation for review by other members of the team who can examine decisions and analytic processes associated with the research. An internal audit may be very useful in multisite studies where it is important to ensure consistency in the research process across the various settings. These activities enhance the research but may not provide sufficient evidence of rigor as typically sought through a more formal or external audit.

External Auditing

Auditing conducted on an external basis involves formal and systematic review carried out by people with no vested interest or involvement in the conduct of the research. An external auditor typically is a researcher knowledgeable in the processes of qualitative research and may or may not have expertise in the subject matter involved in the research. In the typical qualitative study, auditing can be accomplished quite easily by enlisting the assistance of an experienced yet objective colleague and the investigator presenting and defending decision making to that individual. The colleague also can review raw data, notes, logs, journals,

and other materials associated with the study. This process is may be referred to as peer review, although it accomplishes the same goal as an audit.

Timing of an Audit

The actual process of auditing can be initiated at any point in a study. Formative and ongoing auditing occurs while the study is conducted. Auditing also may be carried out on a summative basis at or near the conclusion of the study. Engaging auditors early in the process enables them to provide valuable monitoring throughout various phases of the research. The auditor may even be involved at the initial conceptual stages of the research, providing oversight and reflexive commentary as initial decisions are made regarding the design of the study. Such involvement, however, increases the risk that the auditors might become less neutral themselves due to their engagement with the project and the researcher or research team. Including auditors later in the process may allow for greater neutrality on the part of the auditors. Later involvement, however, creates a greater burden on the researchers to familiarize the auditors with the study and its processes as the auditors will be not be aware of the various nuances and twists that have occurred consistent with the emergent design typical of qualitative research. In the initial contracting with auditors, the researcher should be very clear and detailed about the desired level of involvement and the expectations placed on the auditor or auditing team.

Elements Needed for an Audit

Auditing cannot be accomplished unless there is an appropriate array of materials available for review. The collection of documentation compiled for this purpose during a qualitative study is referred to as an audit trail. Halpern identified six categories of documentation needed to constitute an audit trail. These include raw data, data reduction and analysis products, data reconstruction and synthesis products, notes regarding the processes of the study documentation of the intents and prejudgments or inclinations of the researcher, and information about any instruments used in the study. An organized system of note keeping is essential for this process. For ease of maintaining the audit trail, materials can be grouped into, at minimum, raw data and field notes providing detail of actual encounters with participants; methodological notes regarding data collection processes, interview guides, other

instrumentation, changes in an emergent design; and analytic memos or notes to capture ideas generated during the process of data analysis.

AUTOCORRELATION

Autocorrelation describes sample or population observations or elements that are related to each other across time, space, or other dimensions. Correlated observations are common but problematic, largely because they violate a basic statistical assumption about many samples: independence across elements. Conventional tests of statistical significance assume simple random sampling, in which not only each element has an equal chance of selection but also each combination of elements has an equal chance of selection; autocorrelation violates this assumption. This entry describes common sources of autocorrelation, the problems it can cause, and selected diagnostics and solutions.

Sources

What is the best predictor of a student's 11th-grade academic performance? His or her 10th-grade grade point average. What is the best predictor of this year's crude divorce rate? Usually last year's divorce rate. The old slogan "birds of a feather flock together" describes a college classroom in which students are

about the same age, at the same academic stage, and often in the same disciplinary major. That slogan also describes many residential city blocks, where adult inhabitants have comparable incomes and perhaps even similar marital and parental status. When examining the spread of a disease, such as the H1N1 influenza, researchers often use epidemiological maps showing concentric circles around the initial outbreak locations.

All these are examples of correlated observations, that is, autocorrelation, in which two individuals drawn from a classroom or other group resemble each other more than two individuals drawn from the total population of elements by means of a simple random sample. Correlated observations occur for several reasons:

- Repeated, comparable measures are taken on the same individuals over time, such as many pretest and posttest experimental measures or panel surveys, which reinterview the same individual. Because people remember their prior responses or behaviors, because many behaviors are habitual, and because many traits or talents stay relatively constant over time, these repeated measures become correlated for the same person.
- Time-series measures also apply to larger units, such as birth, divorce, or labor force participation rates in countries or achievement grades in a county school system. Observations on the same variable are repeated on the same unit at some periodic interval (e.g., annual rate of felony crimes). The units transcend the individual, and the periodicity of measurement is usually regular. A lag describes a measure of the same variable on the same unit at an earlier time, frequently one period removed (often called $t - 1$).
- Spatial correlation occurs in cluster samples (e.g., classrooms or neighborhoods). Physically adjacent elements have a higher chance of entering the sample than do other elements. These adjacent elements are typically more similar to already sampled cases than are elements from a simple random sample of the same size.
- A variation of spatial correlation occurs with contagion effects, such as crime incidence (burglars ignore city limits in plundering wealthy neighborhoods) or an outbreak of disease.
- Multiple (repeated) measures administered to the same individual at approximately the same time (e.g., a lengthy survey questionnaire with many Likert-type items in *agree-disagree* format).

Autocorrelation Terms

The terms *positive* or *negative autocorrelation* often apply to time-series data. Societal inertia can inflate the correlation of observed measures across time. The social forces creating trends such as falling marriage rates or rising gross domestic product often carry over from one period into the next. When trends continue over time (e.g., a student's grades), positive predictions can be made from one period to the next, hence the term *positive autocorrelation*.

However, forces at one time can also create compensatory or corrective mechanisms at the next, such as consumers' alternating patterns of "save, then spend" or regulation of production based on estimates of prior inventory. The data points seem to ricochet from one time to the next, so adjacent observations are said to be negatively correlated, creating a cobweb-pattern effect.

The order of the autocorrelation process references the degree of periodicity in correlated observations. When adjacent observations are correlated, the process is *first-order autoregression*, or AR (1). If every other observation, or alternate observations, is correlated, this is an AR (2) process. If every third observation is correlated, this is an AR (3) process, and so on. The order of the process is important, first because the most available diagnostic tests and corrections are for the simplest situation, an AR (1); higher order processes require more complex corrections. Second, the closer two observations are in time or space, the larger the correlation between them, creating more problems for the data analyst. An AR (1) process describes many types of autocorrelation, such as trend data or contagion effects.

Problems

Because the similarity among study elements is more pronounced than that produced by other probability samples, each autocorrelated case "counts less" than a case drawn using simple random sampling. Thus, the "real" or corrected sample size when autocorrelation is present is smaller than a simple random sample containing the same number of elements. This statistical attenuation of the casebase is sometimes called the *design effect*, and it is well known to survey statisticians who design cluster samples.

The sample size is critical in inferential statistics. The N comprises part of the formula for estimates of sample variances and the standard error. The standard error forms the denominator for statistics such as t tests. The N is also used to calculate degrees of freedom

for many statistics, such as F tests in analysis of variance or multiple regression, and it influences the size of chi-square.

When autocorrelation is present, use of the observed N means overestimating the effective n . The calculated variances and standard errors that use simple random sampling formulae (as most statistics computer programs do) are, in fact, too low. In turn, this means t tests and other inferential statistics are too large, leading the analyst to reject the null hypothesis inappropriately. In short, autocorrelation often leads researchers to think that many study results are statistically significant when they are not.

For example, in ordinary least squares (OLS) regression or analysis of variance, autocorrelation renders the simple random sampling formulae invalid for the error terms and measures derived from them. The true sum of squared errors (σ) is now inflated (often considerably) because it is divided by a fraction:

$$\sigma = \Sigma v^2 / (1 - \rho^2),$$

where v is the random component in a residual or error term.

Rho

When elements are correlated, a systematic bias thus enters into estimates of the residuals or error terms. This bias is usually estimated numerically by rho (ρ), the intraclass correlation coefficient, or the correlation of autocorrelation. Rho estimates the average correlation among (usually) adjacent pairs of elements. Rho is found, sometimes unobtrusively, in many statistics that attempt to correct and compensate for autocorrelation, such as hierarchical linear models.

An Example: Autocorrelation Effects on Basic Regression Models

With more complex statistical techniques, such as regression, the effects of ρ multiply beyond providing a less stable estimate of the population mean. If autocorrelation occurs for scores on the dependent variable in OLS regression, then the regression residuals will also be autocorrelated, creating a systematic bias in estimates of the residuals and statistics derived from them. For example, standard computer OLS regression output will be invalid for the following: the residual sum of squares, the standard error of the (regression) estimate, the F test, R^2 and the adjusted R^2 , the standard errors of the B s, the t tests, and significance levels for the B s.

As long as residuals are correlated only among themselves and *not* back with any of the predictor variables, the OLS regression coefficient estimates themselves should be unbiased. However, the B s are no longer *best* linear unbiased estimators, and the estimates of the statistical significance of the B s and the constant term are inaccurate. If there is positive autocorrelation (the more usual case in trend data), the t tests will be inappropriately large. If there is negative autocorrelation (less common), the computer program's calculated t tests will be too small. However, there also may be autocorrelation in an independent variable, which generally aggravates the underestimation of residuals in OLS regression.

Diagnosing First-Order Autocorrelation

There are several ways to detect first-order autocorrelation in least squares analyses. Pairs of adjacent residuals can be plotted against time (or space) and the resulting scatterplot examined. However, the scatterplot "cloud of points" mentioned in most introductory statistics texts often resembles just that, especially with large samples. The decision is literally based on an "eyeball" analysis.

Second, and more formally, the statistical significance of the number of positive and negative runs or sign changes in the residuals can be tested. Tables of significance tests for the runs test are available in many statistics textbooks. The situation of too many runs means the adjacent residuals have switched signs too often and oscillate, resulting in a diagnosis of negative autocorrelation. The situation of too few runs means long streams of positive or negative trends, thus suggesting positive autocorrelation. The number of runs expected in a random progression of elements depends on the number of observations. Most tables apply to relatively small sample sizes, such as $N < 40$. Since many time series for social trends are relatively short in duration, depending on the availability of data, this test can be more practical than it initially appears.

One widely used formal diagnostic for first-order autocorrelation is the Durbin-Watson d statistic, which is available in many statistical computer programs. The d statistic is approximately calculated as $2(1 - \rho)$ where $\rho e_t e_{t-1}$ is the intraclass correlation coefficient. The e_t can be defined as adjacent residuals (in the following formula, v represents the true random error terms that one really wants to estimate):

$$e_t = \rho e_{t-1} + v_t$$

Thus d is a ratio of the sum of squared differences between adjacent residuals to the sum of squared

residuals. The d has an interesting statistical distribution: Values near 2 imply $\rho = 0$ (no autocorrelation); d is 0 when $\rho=1$ (extreme positive autocorrelation) and 4 when $\rho=-1$ (extreme negative autocorrelation). In addition, d has two *zones of indecision* (one near 0 and one near 4), in which the null hypothesis $\rho = 0$ is neither accepted nor rejected. The zones of indecision depend on the number of cases and the number of predictor variables. The d calculation cannot be used with regressions through the origin, with standardized regression equations, or with equations that include lags of the dependent variable as predictors.

Many other computer programs provide iterative estimates of ρ and its standard error, and sometimes the Durbin-Watson d as well. Hierarchical linear models and time-series analysis programs are two examples. The null hypothesis $\rho = 0$ can be tested through a t -distribution with the ratio

$$\rho / \text{se}_{\rho}.$$

The t value can be evaluated using the t tables if needed. If ρ is not statistically significant, there is no first-order autocorrelation. If the analyst is willing to specify the positive or negative direction of the autocorrelation in advance, one-tailed tests of statistical significance are available.

Possible Solutions

When interest centers on a time series and the lag of the dependent variable, it is tempting to attempt solving the autocorrelation problem by simply including a lagged dependent variable (e.g., y_{t-1}) as a predictor in OLS regression or as a covariate in analysis of covariance. Unfortunately, this alternative creates a worse problem. Because the observations are correlated, the residual term e is now correlated back with y_{t-1} , which is a predictor for the regression or analysis of covariance. Not only does this alternative introduce bias into the previously unbiased B coefficient estimates, but using lags also invalidates the use of diagnostic tests such as the Durbin-Watson d .

The first-differences (Cochrane-Orcutt) solution is one way to correct autocorrelation. This generalized least squares (GLS) solution creates a set of new variables by subtracting from each variable (not just the dependent variable) its own $t-1$ lag or adjacent case. Then each newly created variable in the equation is multiplied by the weight $(1-\rho)$ to make the error terms behave randomly.

An analyst may also wish to check for higher order autoregressive processes. If a GLS solution was created

for the AR (1) autocorrelation, some statistical programs will test for the statistical significance of ρ using the Durbin-Watson d for the reestimated GLS equation. If ρ does not equal 0, higher order autocorrelation may exist. Possible solutions here include logarithmic or polynomial transformations of the variables, which may attenuate ρ . The analyst may also wish to examine econometrics programs that estimate higher order autoregressive equations.

In the Cochrane-Orcutt solution, the first observation is lost; this may be problematic in small samples. The Prais-Winsten approximation has been used to estimate the first observation in case of bivariate correlation or regression (with a loss of one additional degree of freedom).

In most social and behavioral science data, once autocorrelation is corrected, conclusions about the statistical significance of the results become much more conservative. Even when corrections for ρ have been made, some statisticians believe that R^2 s or η^2 s to estimate the total explained variance in regression or analysis of variance models are invalid if autocorrelation existed in the original analyses. The explained variance tends to be quite large under these circumstances, reflecting the covariation of trends or behaviors.

Several disciplines have other ways of handling autocorrelation. Some alternate solutions are paired t tests and multivariate analysis of variance for either repeated measures or multiple dependent variables. Econometric analysts diagnose treatments of higher order periodicity, lags for either predictors or dependent variables, and moving averages (often called ARIMA). Specialized computer programs exist, either freestanding or within larger packages, such as the Statistical Package for the Social Sciences (SPSS; an IBM company, formerly called PASW® Statistics).

Autocorrelation is an unexpectedly common phenomenon that occurs in many social and behavioral science phenomena (e.g., psychological experiments or the tracking of student development over time, social trends on employment, or cluster samples). Its major possible consequence—leading one to believe that accidental sample fluctuations are statistically significant—is serious. Checking and correcting for autocorrelation should become a more automatic process in the data analyst's tool chest than it currently appears to be.

B

b PARAMETER

The b parameter is an item response theory (IRT)–based index of item difficulty. As IRT models have become an increasingly common way of modeling item response data, the b parameter has become a popular way of characterizing the difficulty of an individual item, as well as comparing the relative difficulty levels of different items. This entry addresses the b parameter with regard to different IRT models. Further, it discusses interpreting, estimating, and studying the b parameter.

b Parameter Within Different Item Response Theory Models

The precise interpretation of the b parameter is dependent on the specific IRT model within which it is

considered, the most common being the one-parameter logistic (1PL) or Rasch model, the two-parameter logistic (2PL) model, and three-parameter logistic (3PL) model. Under the 1PL model, the b parameter is the single item feature by which items are distinguished in characterizing the likelihood of a correct response. Specifically, the probability of correct response ($X_{ij} = 1$) by examinee i to item j is given by

$$P(X_{ij} = 1) = \frac{\exp(\theta_i - b_j)}{1 + \exp(\theta_i - b_j)},$$

where θ_i represents an ability-level (or trait-level) parameter of the examinee. An interpretation of the b parameter follows from its being attached to the same metric as that assigned to θ .

Usually this metric is continuous and unbounded; the indeterminacy of the metric is often handled by

Figure 1 Item Characteristic Curves for Example Items, One-Parameter Logistic (1PL or Rasch), Two-Parameter Logistic (2PL), and Three-Parameter Logistic (3PL) Models

assigning either the mean of θ (across examinees) or b (across items) to 0. Commonly b parameters will assume values between -3 and 3, with more extreme positive values representing more difficult (or infrequently endorsed) items, and more extreme negative values representing easy (or frequently endorsed) items.

The 2PL and 3PL models include additional item parameters that interact with the b parameter in determining the probability of correct response. The 2PL model adds an item discrimination parameter (a_i), so the probability of correct response is

$$P(X_{ij} = 1) = \frac{\exp[a_i(\theta_i - b_j)]}{1 + \exp[a_i(\theta_i - b_j)]},$$

and the 3PL model adds a lower asymptote (“pseudo-guessing”) parameter, resulting in

$$P(X_{ij} = 1) = c_j + (1 - c_j) \frac{\exp[a_i(\theta_i - b_j)]}{1 + \exp[a_i(\theta_i - b_j)]}.$$

While the same general interpretation of the b parameter as a difficulty parameter still applies under the 2PL and 3PL models, the discrimination and lower asymptote parameters also contribute to the likelihood of a correct response at a given ability level.

Interpretation of the b Parameter

Figure 1 provides an illustration of the b parameter with respect to the 1PL, 2PL, and 3PL models. In this figure, item characteristic curves (ICCs) for three example items are shown with respect to each model. Each curve represents the probability of a correct response as a function of the latent ability level of the examinee. Across all three models, it can be generally seen that as the b parameter increases, the ICC tends to decrease, implying a lower probability of correct response.

In the 1PL and 2PL models, the b parameter has the interpretation of representing the level of the ability or trait at which the respondent has a .50 probability of answering correctly (endorsing the item). For each of the models, the b parameter also identifies the ability level that corresponds to the inflection point of the ICC, and thus the b parameter can be viewed as determining the ability level at which the item is maximally informative. Consequently, the b parameter is a critical element in determining where along the ability continuum an item provides its most effective estimation of ability, and thus the parameter has a strong influence on how items are selected when administered adaptively, such as in a computerized adaptive testing environment.

Under the 1PL model, the b parameter effectively orders all items from easiest to hardest, and this ordering is the same regardless of the examinee ability or

trait level. This property is no longer present in the 2PL and 3PL models, as the ICCs of items may cross, implying a different ordering of item difficulties at different ability levels. This property can also be seen in the example items in Figure 1 in which the ICCs cross for the 2PL and 3PL models, but not for the 1PL model. Consequently, while the b parameter remains the key factor in influencing the difficulty of the item, it is not the sole determinant.

An appealing aspect of the b parameter for all IRT models is that its interpretation is invariant with respect to examinee ability or trait level. That is, its value provides a consistent indicator of item difficulty whether considered for a population of high, medium, or low ability. This property is not present in more classical measures of item difficulty (e.g., “proportion correct”), which are influenced not only by the difficulty of the item, but also by the distribution of ability in the population in which they are administered. This invariance property allows the b parameter to play a fundamental role in how important measurement applications, such as item bias (differential item functioning), test equating, and appropriateness measurement, are conducted and evaluated in an IRT framework.

Estimating the b Parameter

The b parameter is often characterized as a structural parameter within an IRT model and as such will generally be estimated in the process of fitting an IRT model to item response data. Various estimation strategies have been proposed and investigated, some being more appropriate for certain model types. Under the 1PL model, conditional maximum likelihood procedures are common. For all three model types, marginal maximum likelihood, joint maximum likelihood, and Bayesian estimation procedures have been developed and are also commonly used.

Studying the b Parameter

The b parameter can also be the focus of further analysis. Models such as the *linear logistic test model* and its variants attempt to relate the b parameter to task components within an item that account for its difficulty. Such models also provide a way in which the b parameter’s estimates of items can ultimately be used to validate a test instrument. When the b parameter assumes the value expected given an item’s known task components, the parameter provides evidence that the item is functioning as intended by the item writer.

BALANCED INCOMPLETE BLOCK DESIGNS

Block designs are useful in experimental design when the experimental material is not uniform but can be divided into homogeneous blocks. Typically, blocks cannot contain all the treatments, so incomplete block designs are used. The condition of balance, if it can be achieved, guarantees that the designs are optimal in minimizing the variance of treatment differences.

This entry provides a survey of balanced incomplete block designs (BIBDs). It discusses necessary conditions on the parameters for the existence of the designs and optimality results. It also provides a brief introduction to constructions of BIBDs using difference families, finite fields, or recursive methods, and some generalizations, including pointers about what to do if no BIBD is available.

Overview

Balanced incomplete block designs, or BIBDs (known to mathematicians as 2-designs), were introduced into statistics by F. Yates at Rothamsted Experimental Station in 1936. So the introductory example provided in this entry will be a hypothetical agricultural experiment.

Suppose we have seven types of fertilizer, $A, B, \dots, G$, to test. We have land available for the test on seven farms in different regions; each farm can provide three plots for the experiment. The designer's job is to allocate a fertilizer to each of the 21 plots. One possible solution is shown in Table 1.

The farms are represented by columns in the array; the three entries in a column are, in no particular order, the three fertilizers that will be applied to plots on that farm. We refer to the fertilizers as *treatments* and the farms as *blocks*.

Table 1 Possible Solution to Fertilizer Allocation

A	A	A	B	B	C	C
B	D	F	D	E	D	E
C	E	G	F	G	G	F

Figure 1 Fano Plane

This design has several good properties:

1. it is *binary*, that is, the same treatment (fertilizer) is not used more than once in a block;
2. it is *equireplicate*, that is, each treatment is used a constant number of times (3 times); and
3. it is *balanced*, that is, each pair of treatments occur together in a block the same number of times (once).

The design can be specified compactly by regarding each block as a set of three treatments (rather than a set of three plots). This is the way that mathematicians regard such a design, but they use the word *points* in place of *treatments*. A mathematician might represent the design by the diagram shown in Figure 1. This is known to finite geometers as the Fano plane.

The experimental units or plots are not easily visible in this picture; they are what geometers refer to as *flags* (incident point-block pairs). But from the list of blocks, as sets of treatments, we can draw a table similar to the one given earlier; the table entries correspond to the plots.

Definition and Properties

A BIBD consists of a set of v treatments, together with a collection of k -element subsets of the treatment set (blocks), with the property that any two treatments are contained in exactly λ blocks. We require that $1 < k < v$. (If $k = 1$, then no comparisons would be possible; if $k = v$, we would have a *complete block design*, with every treatment in every block.) The earlier introductory example has $v = 7$, $k = 3$, $\lambda = 1$.

Theorem 1. Suppose that a BIBD with parameters v, k, λ as above exists. Then

- it is equireplicate, that is, any treatment occurs in a constant number r of blocks;
- $r(k - 1) = (v - 1)\lambda$; and
- the number b of blocks satisfies $bk = vr$.

This result is proved by straightforward double counting. It follows that $r = (v - 1)\lambda/(k - 1)$ and $b = v$

$(v - 1) \lambda / k (k - 1)$; so a necessary condition for the existence of such a design is that $k - 1$ divides $(v - 1) \lambda$ and k divides $v (v - 1) \lambda$.

The next result is known as *Fisher's inequality*. It rules out the existence of BIBDs with certain parameter sets.

Theorem 2. The numbers v and b of treatments and blocks in a BIBD satisfy $b \geq v$.

If equality holds, then $k = r$, and any two blocks have exactly λ treatments in common.

A BIBD meeting Fisher's bound is referred to as a *symmetric* BIBD. We can form the dual by simply interchanging the labels "treatment" and "block"; the dual of a symmetric BIBD is again a symmetric BIBD.

Optimality

The job of the designer of an experiment like the one in the introductory example is to obtain the maximum possible information from the given experimental material. Typically, block designs are used when comparing v treatments, and bk experimental units are available, which are divided into b blocks of size k . The assumption is that plots within a block are relatively homogeneous but may differ in systematic but unknown ways from plots in a different block. (In the introductory example, different farms may have very different soil and climatic conditions.) In other words, the parameters v , b , and k are given. We wish to estimate differences between treatments as accurately as possible; this means that we want the variances of the estimators to be as small as possible. However, this is a multidimensional optimization problem; we cannot make all variances small simultaneously.

This has led to the introduction of a number of *optimality parameters* which give an overall summary of the variances. The most important are

1. A-optimality, the average variances of treatment differences;
2. D-optimality, the volume of a confidence ellipsoid; and
3. E-optimality, the largest variance of a treatment difference.

In general, different designs might optimize different parameters here. The importance of BIBDs, when they exist, is that they minimize these three parameters and a number of others. The following was shown by Anant M. Kshirgar (1958) and Jack Kiefer (1975).

Theorem 3. Suppose that a BIBD exists for v treatments in b blocks of size k . Then a design for these

parameters minimizes any one of the parameters A, D, and E if and only if it is a BIBD.

So, if a BIBD exists, the designer should use it. If not, the situation is significantly more complicated.

Constructions

Many constructions of BIBDs are known. A few of important ones are mentioned here.

Finite Geometry

These designs are finite analogues of the usual projective and affine (Euclidean) geometry. We work over a finite field with q elements: This is a structure in which the arithmetic operations of addition, subtraction, multiplication, and division (except by zero) are defined and satisfy the usual rules. (It goes back to Évariste Galois, the 19th century mathematician who established that finite fields with q elements exist if and only if q is a prime power.)

The earlier introductory example is of this form. If we represent the treatments $A, \dots, G$ by 3-dimensional vectors over the *binary field* $\{0, 1\}$, specifically $A = 001$, $B = 010$, $C = 011$, $D = 100$, $E = 101$, $F = 110$, $G = 111$, then the blocks are precisely the triples of vectors with sum zero (recall that $1 + 1 = 0$ in the binary field).

Geometries of dimension n over a field with q elements give rise to designs, where we take the blocks to be the m -dimensional subspaces with $0 < m < n$. The number of treatments is $(q^n - 1)/(q - 1)$ for projective geometry and q^n for affine geometry.

Difference Families

In the integers mod 7, represented as $\{0, 1, 2, \dots, 6\}$, the set $\{1, 2, 4\}$ has the property that every nonzero element has a unique representation as the difference (mod 7) between two elements of the set:

$$1 = 2 - 1, 2 = 4 - 2, 3 = 4 - 1, 4 = 1 - 4, \\ 5 = 2 - 4, 6 = 1 - 2.$$

(The set $\{1, 2, 4\}$ is called a *difference set*.) It follows that the translates of $\{1, 2, 4\}$, namely

$$124, 235, 346, 450, 561, 602, 013$$

are the blocks of a symmetric BIBD. This matches the introductory example if we take $1 = A$, $2 = B$, $3 = D$, $4 = C$, $5 = F$, $6 = G$, and $0 = E$.

The construction can be generalized: we can replace the integers mod 7 by an arbitrary group; we can replace the uniqueness property by the property that every nonidentity element has a constant number λ of representations, or we can take a difference family consisting of several sets of the same size, such that each nonidentity element has λ representations as the difference between two elements of the same set.

Recursive Constructions

There are many constructions that build larger BIBDs from smaller ones. These often require the existence of auxiliary structures such as Latin squares or transversal designs. These are complicated and so are not described here.

Existence Theorems

BIBDs were first considered in the 19th century, mostly as a branch of recreational mathematics. Designs with $k = 3$ and $\lambda = 1$ are called *Steiner triple systems*, since the question of their existence was posed by the Swiss geometer Jakob Steiner in 1853; unknown to him, the problem had been solved by Thomas P. Kirkman, the rector of a country parish in the north of England, in 1847 and published in the *Ladies' and Gentlemen's Diary*:

Theorem 4. *A BIBD with $k = 3$ and $\lambda = 1$ on v treatments exists if and only if v is congruent to 1 or 3 mod 6.*

The necessity of the condition follows from our necessary conditions: 2 divides $v - 1$, so v is odd; 3 divides $v(v - 1)$, so v is congruent to 0 or 1 mod 3. The sufficiency was proved by Kirkman by construction, partly direct and partly recursive.

In the 20th century, Haim Hanani showed that, for $k = 3$ and any value of λ , the necessary divisibility conditions are sufficient for the existence of a BIBD. Then in 1975, Richard M. Wilson solved the general existence question asymptotically:

Theorem 5. *There is a number $N(k, \lambda)$ such that, if $k - 1$ divides $(v - 1)\lambda$, k divides $v(v - 1)\lambda$, and $v \geq N(k, \lambda)$, then a BIBD with parameters v, k, λ exists.*

Tables of parameters of BIBDs can be found in a number of places. Marshall Hall's book *Combinatorial Theory* tabulates parameter sets by the replication number r for $r \leq 15$, giving either a construction or a reference to a nonexistence proof in each case.

Resolvability

A block design is *resolvable* if the set of blocks can be partitioned into *resolution classes*, so that the blocks in each class contain each treatment precisely once.

An example, with $v = 9$, $k = 3$ and $\lambda = 1$ (a Steiner triple system) consists of the following blocks:

ABC, DEF, GHI, ADG, BEH, CFI, AEI, BFG,
CDH, AFH, BDI, CEG.

From the definition, we see that the blocks in a resolution class are pairwise disjoint and that the stronger necessary condition that k divides v holds. Kirkman, mentioned earlier, posed his celebrated *schoolgirls problem*, asking for a resolvable BIBD with $v = 15$, $k = 3$, and $\lambda = 1$. He solved this problem himself, but the general case with $k = 3$ and $\lambda = 1$ was not solved until the mid-20th century, when Dijen K. Ray-Chaudhuri and Richard M. Wilson showed that resolvable designs exist whenever v is an odd multiple of 3.

The designs from affine spaces described earlier are resolvable, the resolution classes being *parallel classes* of subspaces of the geometry. Indeed, in the example just given, the blocks are lines of the *affine plane* over the 3-element field.

Resolvable designs can be useful in managing an experiment. If we perform the experiment on the resolution classes in order, then losing (say) the last replication class leaves a block design which is still equireplicate, though no longer balanced.

Generalizations

The concept of BIBD has been generalized in various ways. However, the difference in outlook of statisticians and mathematicians means that many of the mathematical generalizations, though applicable in various fields such as information security, are not relevant to experimental design.

One case of interest to both groups is that of *partially balanced incomplete block designs*, or PBIBDs. There is an association scheme on the set of treatments, such that the concurrence of two treatments (the number of blocks containing both) depends only on the associate class containing the pair. This notion was introduced by Raj Chandra Bose and his students in the 1950s and was widely used since it simplified the computational problem of inverting the information matrix of the design; it also includes many examples of great interest to mathematicians, such as generalized polygons.

Our first condition asserted that BIBDs are binary, that is, a treatment occurs at most once in each block. Relaxing this is difficult for the mathematical approach,

since blocks would have to be multisets rather than sets of treatments, but it is quite natural in experimental design. Indeed, the (nonbinary) design for five treatments in seven blocks of three, with blocks *AAB*, *ACD*, *ACE*, *ADE*, *BCD*, *BCE*, *BDE*, is E-optimal for these parameters (it beats any binary design on this criterion). Since 1995, John. P. Morgan and his students have investigated what they call *variance-balanced designs*, which are E-optimal, and have given necessary and sufficient conditions for their existence when $k = 3$.

BAR CHART

The term *bar chart* refers to a category of diagrams in which values are represented by the height or length of bars, lines, or other symbolic representations. Bar charts are typically used to display variables on a nominal or ordinal scale. Bar charts are a very popular form of information graphics often used in research articles, scientific reports, textbooks, and popular media to visually display relationships and trends in data. However, for this display to be effective, the data must be presented accurately, and the reader must be able to analyze the presentation effectively. This entry provides information on the history of the bar charts, the types of bar charts, and the construction of a bar chart.

History

The creation of the first bar chart is attributed to William Playfair and appeared in *The Commercial and Political Atlas* in 1786. Playfair's bar graph was an adaptation of Joseph Priestley's time-line charts, which were popular at the time. Ironically, Playfair attributed his creation of the bar graph to a lack of data. In his *Atlas*, Playfair presented 34 plates containing line graphs or surface charts graphically representing the imports and exports from different countries over the years. Since he lacked the necessary time-series data for Scotland, he was forced to graph its

trade data for a single year as a series of 34 bars, one for each of the imports and exports of Scotland's 17 trading partners. However, his innovation was largely ignored in Britain for a number of years. Playfair himself attributed little value to his invention, apologizing for what he saw as the limitations of the bar chart. It was not until 1801 and the publication of his *Statistical Breviary* that Playfair recognized the value of his invention. Playfair's invention fared better in Germany and France. In 1811 the German Alexander von Humboldt published adaptations of Playfair's bar graph and pie charts in *Essai Politique sur le Royaume de la Nouvelle Espagne*. In 1821, Jean Baptiste Joseph Fourier adapted the bar chart to create the first graph of cumulative frequency distribution, referred to as an ogive. In 1833, A. M. Guerry used the bar chart to plot crime data, creating the first histogram. Finally, in 1859 Playfair's work began to be accepted in Britain when Stanley Jevons published bar charts in his version of an economic atlas modeled on Playfair's earlier work. Jevons in turn influenced Karl Pearson, commonly considered the "father of modern statistics," who promoted the widespread acceptance of the bar chart and other forms of information graphics.

Types

Although the terms *bar chart* and *bar graph* are now used interchangeably, the term *bar chart* was reserved traditionally for corresponding displays that did not have scales, grid lines, or tick marks. The value each bar represented was instead shown on or adjacent to the data graphic.

An example bar chart is presented in Figure 1. Bar charts can display data by the use of either horizontal or vertical bars; vertical bar charts are also referred to as *column graphs*. The bars are typically of a uniform width with a uniform space between bars. The end of the bar represents the value of the category being plotted. When there is no space between the bars, the graph is referred to as a *joined bar graph* and is used to emphasize the differences between conditions or discrete categories. When continuous quantitative scales are used on both axes of a joined bar chart, the chart is referred to as a *histogram* and is often used to display the distribution of variables that are of interval or ratio scale. If the widths of the bars are not uniform but are instead used to display some measure or characteristic of the data element represented by the bar, the graph is referred to as an *area bar graph* (see Figure 2). In this graph, the heights of the bars represent the total earnings in U.S. dollars, and the widths of the bars are used to represent the percentage of the earnings coming from exports. The information expressed by the bar width can be displayed by means of a scale on the horizontal axis or by a legend, or, as in this case, the values might be noted directly on

Figure 1 Simple Bar Chart and Associated Data

Note: USD = U.S. dollars.

Figure 2 Area Bar Graph and Associated Data

Note: USD = U.S. dollars.

the graph. If both positive and negative values are plotted on the quantitative axis, the graph is called a *deviation graph*. On occasion the bars are replaced with pictures or symbols to make the graph more attractive or to visually represent the data series; these graphs are referred to as *pictographs* or *pictorial bar graphs*.

It may on occasion be desirable to display a confidence interval for the values plotted on the graph. In these cases the confidence intervals can be displayed by appending an error bar, or a shaded, striped, or tapered area to the end of the bar, representing the possible values covered in the confidence interval. If the bars are used to represent the range between the upper and lower values of a data series rather than one specific value, the graph is called a *range bar graph*. Typically the lower values are plotted on the left in a horizontal bar chart and on the bottom for a vertical bar chart. A line drawn across the bar can designate additional or inner values, such as a mean or median value. When the five-number summary (the minimum and maximum values, the upper and lower quartiles, and the median) is displayed, the graph is commonly referred to as a *box plot* or a *box-and-whisker diagram*.

A *simple bar graph* allows the display of a single data series, whereas a *grouped* or *clustered bar graph* displays two or more data series on one graph (see Figure 3). In clustered bar graphs, elements of the same category are plotted side by side; different colors, shades, or patterns, explained in a legend, may be used to differentiate the various data series, and the spaces between clusters distinguish the various categories.

While there is no limit to the number of series that can be plotted on the same graph, it is wise to limit the number of series plotted to no more than four in order to keep the graph from becoming confusing. To reduce the size of the graph and to improve readability, the bars for separate categories can be overlapped, but the overlap should be less than 75% to prevent the graph from being mistaken for a stacked bar graph. A *stacked bar graph*, also called a *divided* or *composite bar graph*, has multiple series stacked end to end instead of side by side. This graph displays the relative contribution of the components of a category; a different color, shade, or pattern differentiates each component, as described in a legend. The end of the bar represents the value of the whole category, and the heights of the various data series represent the relative contribution of the components of the category. If the graph represents the separate components' percentage of the whole value rather than the actual values, this graph is commonly referred to as a *100% stacked bar graph*. Lines can be drawn to connect the components of a stacked bar graph to more clearly delineate the relationship between

the same components of different categories. A stacked bar graph can also use only one bar to demonstrate the contribution of the components of only one category, condition, or occasion, in which case it functions more like a pie chart. Two data series can also be plotted together in a *paired bar graph*, also referred to as a *sliding bar* or *bilateral bar graph*. This graph differs from a clustered bar graph because rather than being plotted side by side, the values for one data series are plotted with horizontal bars to the left and the values for the other data series are plotted with horizontal bars to the right. The units of measurement and scale intervals for the two data series need not be the same, allowing for a visual display of correlations and other meaningful relationships between the two data series. A paired bar graph can be a variation of either a simple, clustered, or stacked bar graph. A paired bar graph without spaces between the bars is often called a *pyramid graph* or a *two-way histogram*. Another method for comparing two data series is the *difference bar graph*. In this type of bar graph, the bars represent the difference in the values of two data series. For instance, one could compare the performance of two different classes on a series of tests or compare the different performance of males and females on a series of assessments. The direction of the difference can be noted at the ends of bars or by labeling the bars. When comparing multiple factors at two points in time or under two different conditions, one can use a *change bar graph*. The bars in this graph are used to represent the change between the two conditions or times. Since the direction of change is usually important with these types of graphs, a coding system is used to indicate the direction of the change.

Creating an Effective Bar Chart

A well-designed bar chart can effectively communicate a substantial amount of information relatively easily, but a poorly designed graph can create confusion and lead to inaccurate conclusions among readers. Choosing the correct graphing format or technique is the first step in creating an effective graphical presentation of data. Bar charts are best used for making discrete comparisons between several categorical variables because the eye can spot very small differences in relative height. However, a bar chart works best with four to six categories; attempting to display more than six categories on a bar graph can lead to a crowded and confusing graph. Once an appropriate graphing technique has been chosen, it is important to choose the direction and the measurement scale for the primary axes. The decision to present the data in a horizontal or vertical format is largely a matter of personal preference; a vertical presentation, however, is more intuitively

Figure 3 Clustered Bar Chart and Associated Data

Note: USD =U.S. dollars.

tive for displaying amount or quantity, and a horizontal presentation makes more sense for displaying distance or time. A horizontal presentation also allows for more space for detailed labeling of the categorical axis. The choice of an appropriate scale is critical for accurate presentation of data in a bar graph. Simple changes in the starting point or the interval of a scale can make the graph look dramatically different and may possibly misrepresent the relationships within the data. The best method for avoiding this problem is to always begin the quantitative scale at 0 and to use a linear rather than a logarithmic scale. However, in cases in which the values to be represented are extremely large, a start value of 0 effectively hides any differences in the data because by necessity the intervals must be extremely wide. In these cases it is possible to maintain smaller intervals while still starting the scale at 0 by the use of a clearly marked scale break. Alternatively, one can highlight the true relationship between the data by starting the scale at 0 and adding an inset of a small section of the larger graph to demonstrate the true relationship. Finally, it is important to make sure the graph and its axes are clearly labeled so that the reader can understand what data are being presented. Modern tech-

nology allows the addition of many superfluous graphical elements to enhance the basic graph design. Although the addition of these elements is a matter of personal choice, it is important to remember that the primary aim of data graphics is to display data accurately and clearly. If the additional elements detract from this clarity of presentation, they should be avoided.

BARTLETT'S TEST

The assumption of equal variances across treatment groups may cause serious problems if violated in one-way analysis of variance models. A common test for homogeneity of variances is Bartlett's test. This statistical test checks whether the variances from different groups (or samples) are equal.

Suppose that there are r treatment groups and we want to test

$$H_0 : \sigma_1^2 = \sigma_2^2 = \cdots = \sigma_r^2$$

versus

$$H_1 : \sigma_m^2 \neq \sigma_k^2 \text{ for some } m \neq k.$$

In this context, we assume that we have independently chosen random samples of size $n_i, i = 1, \dots, r$ from each of the r independent populations. Let $X_{ij} \sim N(\mu_i, \sigma_i^2)$ be independently distributed with a normal distribution having mean μ_i and variance σ_i^2 for each $j = 1, \dots, n_i$ and each $i = 1, \dots, r$. Let $\bar{X}_i$ be the sample mean and S_i^2 the sample variance of the sample taken from the i th group or population. The uniformly most powerful unbiased parametric test of size α for testing for equality of variances among r populations is known as Bartlett's test, and Bartlett's test statistic is given by

$$\ell_1^* = \frac{\prod_{i=1}^r (S_i^2)^{w_i}}{\sum_{i=1}^r w_i S_i^2},$$

where $w_i = (n_i - 1)/(N - r)$ is known as the weight for the i th group and $N = \sum_{i=1}^r n_i$ is the sum of the individual sample sizes. In the equireplicate case (i.e., $n_1 = \cdots = n_r = n$), the weights are equal, and $w_i = 1/r$ for each $i = 1, \dots, r$. The test statistic is the ratio of the *weighted geometric mean* of the group sample variances to their *weighted arithmetic mean*. The values of the test statistic are bounded as $0 \leq \ell_1^* \leq 1$ by Jensen's inequality. Large values of $0 \leq \ell_1^* \leq 1$ (i.e., values near 1) indicate agreement with the null hypothesis, whereas small values indicate disagreement with the null. The terminology ℓ_1^* is used to indicate that Bartlett's test is based on M. S. Bartlett's modification of the likelihood ratio test, wherein he replaced the sample sizes n_i with their corresponding degrees of freedom, $n_i - 1$. Bartlett did so to make the test unbiased. In the equireplicate case, Bartlett's test and the likelihood ratio test result in the same test statistic and same critical region.

The distribution of ℓ_1^* is complex even when the null hypothesis is true. R. E. Glaser showed that the distribution of ℓ_1^* could be expressed as a product of independently distributed beta random variables. In doing so he renewed much interest in the exact distribution of Bartlett's test. We reject H_0 provided $\ell_1^* \leq b_\alpha(n_1, \dots, n_r)$ where $\Pr(\ell_1^* < b_\alpha(n_1, \dots, n_r)) = \alpha$ when H_0 is true. The Bartlett critical value $b_\alpha(n_1, \dots, n_r)$ is indexed by level of significance and the individual sample sizes. The critical values were first tabled in the equireplicate case, and the critical value was simplified to $b_\alpha(n, \dots, n) = b_\alpha(n)$. Tabulating critical values with unequal sample sizes becomes counterproductive because of possible combinations of groups, sample sizes, and levels of significance.

Example

Consider an experiment in which lead levels are measured at five different sites. The data in Table 1 come from Paul Berthouex and Linfield Brown:

Table 1 Ten Measurements of Lead Concentration (mG=L) Measured on Waste Water Specimens

Lab	Measurement No.									
	1	2	3	4	5	6	7	8	9	10
1	3.4	3.0	3.4	5.0	5.1	5.5	5.4	4.2	3.8	4.2
2	4.5	3.7	3.8	3.9	4.3	3.9	4.1	4.0	3.0	4.5
3	5.3	4.7	3.6	5.0	3.6	4.5	4.6	5.3	3.9	4.1
4	3.2	3.4	3.1	3.0	3.9	2.0	1.9	2.7	3.8	4.2
5	3.3	2.4	2.7	3.2	3.3	2.9	4.4	3.4	4.8	3.0

Source: Berthouex, P. M., & Brown, L. C. (2002). *Statistics for environmental engineers* (2nd ed., p. 170). Boca Raton, FL: Lewis.

From these data one can compute the sample variances and weights, which are:

<i>Labs</i>	<i>Weight</i>	<i>Variance</i>
1	0.2	0.81778
2	0.2	0.19344
3	0.2	0.41156
4	0.2	0.58400
5	0.2	0.54267

By substituting these values into the formula for ℓ_1^* , we obtain

$$\ell_1^* = \frac{0.46016}{0.509889} = 0.90248$$

Critical values, $b_\alpha(\alpha, n)$ of Bartlett's test are tabled for cases in which the sample sizes are equal and $\alpha = .05$.

Note: The table shows the critical values used in Bartlett's test of equal variance at the 5% level of significance.

These values are given in D. Dyer and Jerome Keating for various values of r , the number of groups, and n , the common sample size (see Table 2). Works by Glaser, M. T. Chao, and Glaser, and S. B. Nandi provide tables of exact critical values of Bartlett's test. The most extensive set is contained in Dyer and Keating. Extensions (for larger numbers of groups) to the table of critical values can be found in Keating, Glaser, and N. S. Ketchum.

Approximation

In the event that the sample sizes are not equal, one can use the *Dyer-Keating approximation* to the critical values:

$$b_a(a; n_1, \dots, n_a) \doteq \sum_{i=1}^a \frac{n_i}{N} \times b_a(a, n_i).$$

So for the lead levels, we have the following values: $b_{0.05}(5; 10) \doteq 0.8025$. At the 5% level of significance, there is not enough evidence to reject the null hypothesis of equal variances.

Because of the complexity of the distribution of ℓ_1^* , Bartlett's test originally employed an approximation. Bartlett proved that

$$[-\ln(\ell_1^*)]/c \sim \chi^2(r-1),$$

where

$$c = \frac{1 + \left[\frac{1}{3(r-1)} \right] \sum_{i=1}^r \frac{1}{n_i - 1} - \frac{1}{N - r}}{N - r}.$$

The approximation works poorly for small sample sizes. This approximation is more accurate as sample sizes increase, and it is recommended that $\min(n_i) \geq 3$ and that most $n_i > 5$.

Assumptions

Bartlett's test statistic is quite sensitive to nonnormality. In fact, W. J. Conover, M. E. Johnson, and M. M. Johnson echo the results of G. E. P. Box that Bartlett's test is very sensitive to samples that exhibit nonnormal kurtosis. They recommend that Bartlett's test be used only when the data conform to normality. Prior to using Bartlett's test, it is recommended that one test for normality using an appropriate test such as the Shapiro-Wilk W test. In the event that the normality assumption is violated, it is recommended that one test equality of variances using Howard Levene's test.

BARYCENTRIC DISCRIMINANT ANALYSIS

Barycentric discriminant analysis (BADA) generalizes discriminant analysis, and like discriminant analysis, it is performed when measurements made on some observations are combined to assign these observations, or *new* observations, to a priori defined categories. For example, BADA can be used (a) to assign people to a given diagnostic group (e.g., patients with Alzheimer's disease, patients with other dementia, or people aging without dementia) on the basis of brain imaging data or psychological tests (here the a priori categories are the clinical groups), (b) to assign wines to a region of production on the basis of

several physical and chemical measurements (here the a priori categories are the regions of production), (c) to use brain scans taken on a given participant to determine what type of object (e.g., a face, a cat, a chair) was watched by the participant when the scans were taken (here the a priori categories are the types of object), or (d) to use DNA measurements to predict whether a person is at risk for a given health problem (here the a priori categories are the types of health problem).

BADA is more general than standard discriminant analysis because it can be used in cases for which discriminant analysis cannot be used. This is the case, for example, when there are more variables than observations, when the predictors are colinear, or when the measurements are categorical.

BADA is a class of methods that all rely on the same principle: Each category of interest is represented by the *barycenter* of its observations (i.e., the weighted average of the observations of a given category; the barycenter is also called the *center of gravity* or *center of mass*), and a generalized principal components analysis (GPCA) is performed on the category by variable matrix. This analysis gives a set of discriminant factor scores for the categories and another set of factor scores for the variables. The original observations are then projected onto the category factor space, providing a set of factor scores for the observations. The distance of each observation to the set of categories is computed from the factor scores, and each observation is assigned to the closest category. The a priori and a posteriori category assignments are compared to assess the quality of the discriminant procedure. The prediction for the observations that were used to compute the barycenters is called the *fixed-effect prediction*. The fixed-effect performance is evaluated by counting the number of correct and incorrect assignments and storing these numbers in a confusion matrix. Another index of the performance of the fixed-effect model—equivalent to a squared coefficient of correlation—is the ratio of the category variance to the sum of the category variance and the variance of the observations within each category. This coefficient is denoted R^2 and is interpreted as the proportion of variance of the observations explained by the categories or as the proportion of the variance explained by the discriminant model. The performance of the fixed-effect model can also be represented graphically as a *tolerance ellipsoid* that encompasses a given proportion (say 95%) of the observations. The overlap between the tolerance ellipsoids of two categories is proportional to the number of misclassifications between these two categories.

New observations can also be projected onto the discriminant factor space, and they can be assigned to the closest category. When the actual assignment of these observations is not known, the model can be used to *predict* category membership. The model is then called a

random model (as opposed to the fixed model). An obvious problem, then, is to evaluate the quality of the prediction for new observations. Ideally, the performance of the random-effect model is evaluated by counting the number of correct and incorrect classifications for new observations and computing a confusion matrix based on these new observations. However, it is not always practical or even feasible to obtain new observations, and therefore the random-effect performance is often evaluated using computational cross-validation techniques such as the *leave one out* (LOO) or the *bootstrap*. For example, an LOO approach can be used by which each observation is taken out of the set, in turn, and predicted from the model built on all the other observations. The predicted observations are then projected in the space of the fixed-effect discriminant scores. This can also be represented graphically as a *prediction ellipsoid*. A prediction ellipsoid encompasses a given proportion (say 95%) of the new observations. The overlap between the prediction ellipsoids of two categories is proportional to the number of misclassifications of new observations between these two categories.

The stability of the discriminant model can be assessed by a cross-validation model such as the bootstrap. In this procedure, multiple sets of observations are generated by sampling with replacement from the original set of observations, and the category barycenters are computed from each of these sets. These barycenters are then projected onto the discriminant factor scores. The variability of the barycenters can be represented graphically as a *confidence ellipsoid* that encompasses a given proportion (say 95%) of the barycenters. When the confidence intervals of two categories do not overlap, these two categories are significantly different.

In summary, BADA is a GPCA performed on the category barycenters. GPCA encompasses various techniques, such as correspondence analysis, biplot, Hellinger distance analysis, discriminant analysis, and canonical variate analysis. For each specific type of GPCA, there is a corresponding version of BADA. For example, when the GPCA is correspondence analysis, this gives the most well-known version of BADA: discriminant correspondence analysis. Because BADA is based on GPCA, it can also analyze data tables obtained by the concatenation of blocks (i.e., subtables). In this case, the importance (often called the *contribution*) of each block to the overall discrimination can also be evaluated and represented as a graph.

BASKET TRIALS DESIGN

Basket trials test a therapeutic intervention for several different disease *indications* simultaneously in the same clinical trial. Indications are grouped together in a basket because they share a molecular marker or a disease mechanism believed to be predictive of clinical benefit from the therapeutic intervention under study. Basket trials are a type of master protocol, a class of clinical designs that investigate several hypotheses concurrently. Master protocols include basket trials, whereby one therapy is tested in multiple indications; umbrella trials, whereby multiple therapies are tested in one indication; and platform trials, whereby multiple therapies enter and exit an ongoing study in an assembly-line fashion.

This entry summarizes the motivation for using master protocols, metrics for basket trial performance evaluation, advantages and limitations of basket trials, and types of basket trials.

Motivation

Master protocols address the high cost and long time required for clinical drug development, the process of testing safety and effectiveness for therapies, to facilitate approval by national health authorities for patient use. The total cost of developing a new therapy, including basic research, medicinal chemistry, animal efficacy and toxicology, and clinical development, is estimated at approximately US\$ 1 billion, including the cost of failed attempts. The resulting high cost of therapy means patients often cannot afford needed medications and must choose between medications and other basic necessities. The total time for development is a decade or longer. During this waiting period, patients facing debilitating and/or life-threatening diseases may have their medical

needs unmet. By investigating several hypotheses at once, master protocols aim to reduce these severe cost and time issues. Alternatively, the savings may be utilized to more thoroughly investigate optimal dosing, scheduling, and matching of therapies to patient subpopulations, rather than to reduce cost and development time.

Performance Evaluation

The performance metrics discussed in this section provide a framework for comparing possible basket trials designs. Because basket trials are complex, it is usually not possible to write mathematical formulas for their performance. The performance is evaluated by computer simulation, in which the trial is simulated numerous times with chance variation, and the results observed.

False Positive Rate

For conventional clinical trials, the definition of the false positive rate is relatively simple. If investigators execute the clinical trial for a therapy that is actually ineffective in the proposed indication, the false positive rate is the proportion of times the trial will falsely reach the conclusion that the therapy is effective, due to the play of chance. However, for basket trials, the situation is more complicated, in that the therapy is being tested in multiple indications at once. A *positive basket* may be defined as a basket for which the drug is actually effective in one or more indications, and a *negative basket* as one in which the drug is actually ineffective in all indications. The *false positive rate by basket* is then the proportion of times among evaluations of a negative basket that the trial falsely concludes that it is positive. A more stringent approach is the *false positive rate by indication*. In this approach, each indication is defined as positive or negative by whether the therapy is actually effective or ineffective in that indication. The *false positive rate by indication* is the probability that a negative indication will be falsely considered positive by the study.

An important controversy in the field is whether (and when) control of false positive rates by indication is required in basket trials. The indications are subgroups of the overall basket. In a conventional clinical trial, control of the false positive rate by subgroups is not required. But basket trials feature nontraditional groupings, in which molecular characteristics that normally define subgroups define the overall group, and diseases which are traditionally considered different are grouped as one.

False Negative Rate

In analogy with the false positive rate, the *false negative rate by basket* is the proportion of times in

evaluating a positive basket that the trial design will, by the play of chance, falsely conclude it is negative. The more stringent *false negative rate by indication* is the proportion of times a positive individual indication will be falsely considered to be negative by the study. *Power* is one minus the false negative rate.

Efficiency

Efficiency is an important metric for any master protocol. It normalizes (divides) a results metric by a cost metric, such as financial cost or number of trial participants. Although power is a popular performance indicator, it is possible to increase the power of a study to any desired level by increasing the sample size. Yet, for each constant increment in power, a progressively higher cost must be paid in sample size, and the efficiency decreases due to the diminishing returns.

The choice of results and cost metrics is varied and depends on the situation. Moreover, the concept of efficiency applies not only to individual therapies and indications but to a portfolio of many therapies and indications. In some instances, with finite resources, it may be wise to invest less in one trial to preserve resources for another.

Advantages

Basket trials group multiple indications together as one. Under ideal conditions, a basket trial consisting of k indications can offer a nearly k -fold increase in efficiency. This increase in efficiency is potentially greater than other master protocols. Even if control of the false positive rate by indication is required, a 40% increase in efficiency may be achieved with optimization.

Basket trials typically study only one therapy, and therefore they can be conducted by a single sponsor, avoiding the complex negotiations between multiple sponsors required for other master protocols.

Limitations

Basket trials assume that the indications within the basket will have similar responses to the therapy, due to the shared marker or mechanism. However, this is not always true. The drug may work in melanoma with a given mutation but not in colon cancer with the same mutation. This heterogeneity can result in false positives and false negatives when data are pooled across indications.

Much of basket trial methodology is aimed at minimizing heterogeneity. In *adaptive basket designs*, interim study data are used to minimize heterogeneity. The final result is judged on a grouping that is more likely to be homogeneous; other indications may be discarded.

Types of Basket Trials

Basket trials may be randomized controlled or single arm. Randomized controlled trials are more conclusive in that they minimize biased selection of participants as well as biases due to improvements in supportive care and diagnostic technologies which affect comparisons of single-arm results to historical controls.

Basket trials also differ in the degree to which data from different indications are pooled. In early basket trials, the data were not pooled, and thus the studies were primarily a useful administrative strategy for rare diseases. Most current designs either fully pool the data or utilize partial pooling calibrated by the degree of similarity in the results (*information borrowing*).

Basket trials have been applied mostly to the *exploratory phase* of clinical development, which involves early safety and efficacy data and dose/schedule optimization. In contrast, applications in the *confirmatory phase* of development, where large studies are usually performed to obtain statistical proof of efficacy, have been limited to special cases supported by extraordinary scientific evidence, and/or unusual efficacy in conditions with limited or no other medical options. In these settings, single-arm designs, small sample sizes, and short-term binary end points with uncertain relationship to definitive end points like survival are appropriate even in the confirmatory phase, facilitating application of basket designs.

Cost and time savings would be greater if basket trials could be applied generally to the resource-intensive confirmatory space. A randomized controlled confirmatory basket trial design has been proposed, and the false positive rate can be strictly controlled as required in the confirmatory space. The design can be further modified to achieve control of the false positive rate by indication. Nonetheless, whether the design can be confirmatory despite possible differences in the control arms and the natural histories of the indications may depend on the strength of scientific and medical evidence for pooling.

BAYES'S THEOREM

Bayes's theorem is a simple mathematical formula used for calculating conditional probabilities. It figures prominently in subjectivist or Bayesian approaches to statistics, epistemology, and inductive logic. Subjectivists, who maintain that rational belief is governed by the laws of probability, lean heavily on conditional probabilities in their theories of evidence and their models of empirical learning. Bayes's theorem is central to these paradigms because it simplifies the calculation of conditional probabilities and clarifies significant features of the subjectivist position.

This entry begins with a brief history of Thomas Bayes and the publication of his theorem. Next, the entry focuses on probability and its role in Bayes's theorem. Last, the entry explores modern applications of Bayes's theorem.

History

Thomas Bayes was born in 1702, probably in London, England. Others have suggested the place of his birth to be Hertfordshire. He was the eldest of six children of Joshua and Ann Carpenter Bayes. His father was a non-conformist minister, one of the first seven in England. Information on Bayes's childhood is scarce. Some sources state that he was privately educated, and others state he received a liberal education to prepare for the ministry. After assisting his father for many years, he spent his adult life as a Presbyterian minister at the chapel in Tunbridge Wells. In 1742, Bayes was elected as a fellow by the Royal Society of London. He retired in 1752 and remained in Tunbridge Wells until his death in April 1761.

Throughout his life he wrote very little, and only two of his works are known to have been published. These two essays are *Divine Benevolence*, published in 1731,

and *Introduction to the Doctrine of Fluxions*, published in 1736. He was known as a mathematician not for these essays but for two other papers he had written but never published. His studies focused in the areas of probability and statistics. His posthumously published article now known by the title "An Essay Towards Solving a Problem in the Doctrine of Chances" developed the idea of inverse probability, which later became associated with his name as Bayes's theorem. Inverse probability was so called because it involves inferring backward from the data to the parameter (i.e., from the effect to the cause). Initially, Bayes's ideas attracted little attention. It was not until after the French mathematician Pierre-Simon Laplace published his paper "Mémoire sur la Probabilité des Causes par les Événements" in 1774 that Bayes's ideas gained wider attention. Laplace extended the use of inverse probability to a variety of distributions and introduced the notion of "indifference" as a means of specifying prior distributions in the absence of prior knowledge. Inverse probability became during the 19th century the most commonly used method for making statistical inferences. Some of the more famous examples of the use of inverse probability to draw inferences during this period include estimation of the mass of Saturn, the probability of the birth of a boy at different locations, the utility of antiseptics, and the accuracy of judicial decisions.

In the latter half of the 19th century, authorities such as Siméon-Denis Poisson, Bernard Bolzano, Robert Leslie Ellis, Jakob Friedrich Fries, John Stuart Mill, and A. A. Cournot began to make distinctions between probabilities about things and probabilities involving our beliefs about things. Some of these authors attached the terms *objective* and *subjective* to the two types of probability. Toward the end of the century, Karl Pearson, in his *Grammar of Science*, argued for using experience to determine prior distributions, an approach that eventually evolved into what is now known as *empirical Bayes*. The Bayesian idea of inverse probability was also being challenged toward the end of the 19th century, with the criticism focusing on the use of uniform or "indifference" prior distributions to express a lack of prior knowledge.

The criticism of Bayesian ideas spurred research into statistical methods that did not rely on prior knowledge and the choice of prior distributions. In 1922, Ronald Alymer Fisher's paper "On the Mathematical Foundations of Theoretical Statistics," which introduced the idea of likelihood and maximum likelihood estimates, revolutionized modern statistical thinking. Jerzy Neyman and Egon Pearson extended Fisher's work by adding the ideas of hypothesis testing and confidence intervals. Eventually the collective work of Fisher, Neyman, and Pearson became known as *frequentist* methods. From the 1920s to the 1950s, frequentist methods displaced inverse probability as the primary methods used by researchers to make statistical inferences.

Interest in using Bayesian methods for statistical inference revived in the 1950s, inspired by Leonard Jimmie Savage's 1954 book *The Foundations of Statistics*. Savage's work built on previous work of several earlier authors exploring the idea of subjective probability, in particular the work of Bruno de Finetti. It was during this time that the terms *Bayesian* and *frequentist* began to be used to refer to the two statistical inference camps. The number of papers and authors using Bayesian statistics continued to grow in the 1960s. Examples of Bayesian research from this period include an investigation by Frederick Mosteller and David Wallace into the authorship of several of the Federalist papers and the use of Bayesian methods to estimate the parameters of time-series models. The introduction of Monte Carlo Markov chain (MCMC) methods to the Bayesian world in the late 1980s made computations that were impractical or impossible earlier realistic and relatively easy. The result has been a resurgence of interest in the use of Bayesian methods to draw statistical inferences.

Publishing of Bayes's Theorem

Bayes never published his mathematical papers, and therein lies a mystery. Some suggest his theological concerns with modesty might have played a role in his decision. However, after Bayes's death, his family asked Richard Price to examine Bayes's work. Price was responsible for the communication of Bayes's essay on probability and chance to the Royal Society. Although Price was making Bayes's work known, he was occasionally mistaken for the author of the essays and for a time received credit for them. In fact, Price only added introductions and appendixes to works he had published for Bayes, although he would eventually write a follow-up paper to Bayes's work.

The present form of Bayes's theorem was actually derived not by Bayes but by Laplace. Laplace used the information provided by Bayes to construct the theorem in 1774. Only in later papers did Laplace acknowledge Bayes's work.

Inspiration of Bayes's Theorem

In "An Essay Towards Solving a Problem in the Doctrine of Chances," Bayes posed a problem to be solved: "Given the number of times in which an unknown event has happened and failed: *Required* the chance that the probability of its happening in a single trial lies somewhere between any two degrees of probability that can be named." Bayes's reasoning began with the idea of conditional probability:

If $P(B) > 0$, the conditional probability of A given B , denoted by $P(A|B)$, is

$$P(A|B) = \frac{P(A \cap B)}{P(B)} \text{ or } \frac{P(AB)}{P(B)}.$$

Bayes's main focus then became defining $P(B|A)$ in terms of $P(A|B)$.

A key component that Bayes needed was the *law of total probability*. Sometimes it is not possible to calculate the probability of the occurrence of an event A . However, it is possible to find $P(A|B)$ and $P(A|B^c)$ for some event B where B^c is the complement of B . The weighted average, $P(A)$, of the probability of A given that B has occurred and the probability of A given that B has not occurred can be defined as follows:

Let B be an event with $P(B) > 0$ and $P(B^c) > 0$. Then for any event A ,

$$P(A) = P(A|B)P(B) + P(A|B^c)P(B^c).$$

If there are k events, $B_1, \dots, B_k$, that form a partition of the sample space, and A is another event in the sample space, then the events $B_1A, B_2A, \dots, B_kA$ will form a partition of A . Thus, the law of total probability can be extended as follows:

Let B_j be an event with $P(B_j) > 0$ for $j = 1, \dots, k$. Then for any event A ,

$$P(A) = \sum_{j=1}^k P(B_j)P(A|B_j).$$

These basic rules of probability served as the inspiration for Bayes's theorem.

Bayes's Theorem

Bayes's theorem allows for a reduction in uncertainty by considering events that have occurred. The theorem is applicable as long as the probability of the more recent event (given an earlier event) is known. With this theorem, one can find the probability of the earlier event, given the more recent event that has occurred. The earlier event is known as the *prior* probability. The primary focus is on the probability of the earlier event given the more recent event that has occurred (called the *posterior* probability). The theorem can be described in the following manner:

Let B_i be an event with $P(B_i) > 0$ for $j = 1, \dots, k$ and forming a partition of the sample space. Furthermore, let A be an event such that $P(A) > 0$. Then for $i = 1, \dots, k$,

$$P(B_i|A) = \frac{P(B_i)P(A|B_i)}{\sum_{j=1}^k P(B_j)P(A|B_j)}.$$

$P(B_i)$ is the *prior* probability and the probability of the earlier event. $P(A|B_i)$ is the probability of the more recent event given the prior has occurred and is referred

to as the *likelihood*. $P(B_i | A)$ is what one is solving for and is the probability of the earlier event given that the recent event has occurred (the posterior probability). There is also a version of Bayes's theorem based on a secondary event C :

$$P(B_i | AC) = \frac{P(B_i | C)P(A | B_i C)}{\sum_{j=1}^k P(B_j | C)P(A | B_j C)}.$$

Example

A box contains 7 red and 13 blue balls. Two balls are selected at random and are discarded without their colors being seen. If a third ball is drawn randomly and observed to be red, what is the probability that both of the discarded balls were blue?

Let BB , BR , and RR represent the events that the discarded balls are blue and blue, blue and red, and red and red, respectively. Let R represent the event that the third ball chosen is red. Solve for the posterior probability $P(BB | R)$.

$$P(BB | R) =$$

$$\frac{P(R | BB)P(BB)}{P(R | BB)P(BB) + P(R | BR)P(BR) + P(R | RR)P(RR)}$$

The probability that the first two balls drawn were blue, red, or blue and red are 39/95, 21/190, and 91/190, in that order. Now,

$$P(BB | R) = \frac{\frac{7}{18} * \frac{39}{95}}{\frac{7}{18} * \frac{39}{95} + \frac{6}{18} * \frac{91}{190} + \frac{5}{18} * \frac{21}{190}} \approx 0.46$$

The probability that the first two balls chosen were blue given the third ball selected was red is approximately 46%.

Bayes's theorem can be applied to the real world to make appropriate estimations of probability in a given situation. Diagnostic testing is one example in which the theorem is a useful tool. Diagnostic testing identifies whether a person has a particular disease. However, these tests contain error. Thus, a person can test positive for the disease and in actuality not be carrying the disease. Bayes's theorem can be used to estimate the probability that a person truly has the disease given that the person tests positive. As an illustration of this, suppose that a particular cancer is found for every 1 person in 2,000. Furthermore, if a person has the disease, there is a 90% chance the diagnostic procedure will result in a positive identification. If a person does not have the disease, the test will give a false positive 1% of the time. Using Bayes's theorem, the probability that a person with a positive test result actually has the cancer (C), is

$$P(C | P) = \frac{\frac{1}{2000}(.90)}{\frac{1}{2000}(.90) + \frac{1999}{2000}(.01)} \approx 0.043.$$

If a person tests positive for the cancer test, there is only a 4% chance that the person has the cancer. Consequently, follow-up tests are almost always necessary to verify a positive finding with medical screening tests.

Bayes's theorem has also been used in psychometrics to make a classification scale rather than an ability scale in the classroom. A simple example of classification is dividing a population into two categories of mastery and nonmastery of a subject. A test would be devised to determine whether a person falls in the mastery or the nonmastery category. The posterior probabilities for different skills can be collected, and the results would show mastered skills and nonmastered skills that need attention. The test may even allow for new posterior probabilities to be computed after each question.

The two examples presented above are just a small sample of the applications in which Bayes's theorem has been useful. While certain academic fields concentrate on its use more than others do, the theorem has far-reaching influence in business, medicine, education, psychology, and so on.

Bayesian Statistical Inference

Bayes's theorem provides a foundation for Bayesian statistical inference. However, the approach to inference is different from that of a traditional (frequentist) point of view. With Bayes's theorem, inference is dynamic. That is, a Bayesian approach uses evidence about a phenomenon to update knowledge of prior beliefs.

There are two popular ways to approach inference. The traditional way is the frequentist approach, in which the probability P of an uncertain event A , written $P(A)$, is defined by the frequency of that event, based on previous observations. In general, population parameters are considered as fixed effects and do not have distributional form. The frequentist approach to defining the probability of an uncertain event is sufficient, provided that one has been able to record accurate information about many past instances of the event. However, if no such historical database exists, then a different approach must be considered.

Bayesian inference is an approach that allows one to reason about beliefs under conditions of uncertainty. Different people may have different beliefs about the probability of a prior event, depending on their specific knowledge of factors that might affect its likelihood. Thus, Bayesian inference has no one correct probability or approach. Bayesian inference is dependent on both prior and observed data.

In a traditional hypothesis test, there are two complementary hypotheses: H_0 , the status quo hypothesis, and H_1 , the hypothesis of change. Letting D stand for the observed data, Bayes's theorem applied to the hypotheses becomes

$$P(H_0 | D) = \frac{P(H_0)P(D | H_0)}{P(H_0)P(D | H_0) + P(H_1)P(D | H_1)}$$

and

$$P(H_1 | D) = \frac{P(H_1)P(D | H_1)}{P(H_0)P(D | H_0) + P(H_1)P(D | H_1)}.$$

The $P(H_0 | D)$ and $P(H_1 | D)$ are posterior probabilities (i.e., the probability that the null is true given the data and the probability that the alternative is true given the data, respectively). The $P(H_0)$ and $P(H_1)$ are prior probabilities (i.e., the probability that the null or the alternative is true prior to considering the new data, respectively).

In frequentist hypothesis testing, one considers only $P(D | H_0)$, which is called the *p value*. If the *p* value is smaller than a predetermined significance level, then one rejects the null hypothesis and asserts the alternative hypothesis. One common mistake is to interpret the *p* value as the probability that the null hypothesis is true, given the observed data. This interpretation is a Bayesian one. From a Bayesian perspective, one may obtain $P(H_0 | D)$, and if that probability is sufficiently small, then one rejects the null hypothesis in favor of the alternative hypothesis. In addition, with a Bayesian approach, several alternative hypotheses can be considered at one time.

As with traditional frequentist confidence intervals, a *credible interval* can be computed in Bayesian statistics. This credible interval is defined as the posterior probability interval and is used in ways similar to the uses of confidence intervals in frequentist statistics. For example, a 95% credible interval means that the posterior probability of the parameter lying in the given range is 0.95. A frequentist 95% confidence interval means that with a large number of repeated samples, 95% of the calculated confidence intervals would include the true value of the parameter; yet the probability that the parameter is inside the actual calculated confidence interval is either 0 or 1. In general, Bayesian credible intervals do not match a frequentist confidence interval, since the credible interval incorporates information from the prior distribution whereas confidence intervals are based only on the data.

Modern Applications

In Bayesian statistics, information about the data and a priori information are combined to estimate the posterior distribution of the parameters. This posterior distribution is used to infer the values of the parameters,

along with the associated uncertainty. Multiple tests and predictions can be performed simultaneously and flexibly. Quantities of interest that are functions of the parameters are straightforward to estimate, again including the uncertainty. Posterior inferences can be updated as more data are obtained, so study design is more flexible than for frequentist methods.

Bayesian inference is possible in a number of contexts in which frequentist methods are deficient. For instance, Bayesian inference can be performed with small data sets. More broadly, Bayesian statistics is useful when the data set may be large but when few data points are associated with a particular treatment. In such situations standard frequentist estimators can be inappropriate because the likelihood may not be well approximated by a normal distribution. The use of Bayesian statistics also allows for the incorporation of prior information and for simultaneous inference using data from multiple studies. Inference is also possible for complex hierarchical models.

Lately, computation for Bayesian models is most often done via MCMC techniques, which obtain dependent samples from the posterior distribution of the parameters. In MCMC, a set of initial parameter values is chosen. These parameter values are then iteratively updated via a specially constructed Markovian transition. In the limit of the number of iterations, the parameter values are distributed according to the posterior distribution. In practice, after approximate convergence of the Markov chain, the time series of sets of parameter values can be stored and then used for inference via empirical averaging (i.e., Monte Carlo). The accuracy of this empirical averaging depends on the effective sample size of the stored parameter values, that is, the number of iterations of the chain after convergence, adjusted for the autocorrelation of the chain. One method of specifying the Markovian transition is via Metropolis–Hastings, which proposes a change in the parameters, often according to a random walk (the assumption that many unpredictable small fluctuations will occur in a chain of events), and then accepts or rejects that move with a probability that is dependent on the current and proposed state.

In order to perform valid inference, the Markov chain must have approximately converged to the posterior distribution before the samples are stored and used for inference. In addition, enough samples must be stored after convergence to have a large effective sample size; if the autocorrelation of the chain is high, then the number of samples needs to be large. Lack of convergence or high autocorrelation of the chain is detected via convergence diagnostics, which include autocorrelation and trace plots, as well as Geweke, Gelman–Rubin, and Heidelberger–Welch diagnostics. Software for MCMC can also be validated by a distinct set of techniques.

These techniques compare the posterior samples drawn by the software with samples from the prior and the data model, thereby validating the joint distribution of the data and parameters as estimated by the software.

BAYESIAN ADAPTIVE RANDOMIZATION DESIGN

The Bayesian adaptive randomization design is an extension of adaptive research designs, which modify the randomization ratio during a study in order to maximize individual participant outcomes. Bayesian adaptive randomization designs use Bayesian data

analysis to estimate the probability that each intervention maximizes the outcome of interest, and the randomization ratio is adjusted according to these estimates. In adjusting the randomization ratio based on which intervention is estimated to produce the most favorable outcome, Bayesian adaptive randomization designs maximize the likelihood of participants experiencing positive outcomes and minimize the likelihood of participants experiencing poor outcomes.

Bayesian adaptive randomization designs follow a four-step procedure. In Step 1, participants are randomly allocated to one of the interventions with the probability of allocation into each intervention being specified by the randomization ratio. In Step 2, participants' outcome data are collected. In Step 3, the probability that each intervention produces the most favorable outcome is estimated with Bayesian data analysis. In Step 4, the randomization ratio is updated. Steps 1–4 are then repeated until either the desired number of participants has been recruited or one of the interventions has shown convincing evidence of producing the most favorable outcome.

This entry goes on to provide an examination of adaptive randomization ratios, two primary assumptions made by Bayesian adaptive randomization design, and logical considerations. Various types of data used in Bayesian data analysis are introduced, and the steps of early and late randomizations are then explained. The entry concludes by listing some advantages and limitations of Bayesian adaptive randomization design, followed by an example of a hypothetical study implementing a two-group Bayesian adaptive randomization design.

Adaptive Randomization Ratios

Most randomized study designs use a fixed randomization ratio, but Bayesian adaptive randomization designs implement an adaptive randomization ratio. A randomization ratio is defined as a ratio of the probabilities of being randomly allocated to each of the interventions. A fixed randomization ratio is held constant throughout the study, but an adaptive randomization ratio can change during the study.

To better understand randomization ratios—both fixed and adaptive—consider a two-group study. In this example and throughout the remainder of this entry, it is assumed that each group is implementing a different intervention. Researchers may consider a research design using a 1:1 fixed randomization ratio, which indicates a 50% chance a participant is allocated into the first group and a 50% chance a participant is allocated into the second group. Researchers may also consider a research design using an adaptive randomization ratio. The adaptive randomization ratio may be 1:1

during the early stages of the study, but the randomization ratio could change during the course of the study if collected data indicate one of the groups' interventions produces better outcomes.

Assumptions

Bayesian adaptive randomization designs make two primary assumptions. First, the randomization of participants must be dispersed throughout the course of the study, such that the outcome data collection for some participants occurs before the randomization of other participants. Because Bayesian adaptive randomization designs use participants' results to inform future randomizations, some participants must be randomized after collecting data from previous participants to maximize individual participant outcomes. If all the participants are randomized simultaneously, Bayesian adaptive randomization designs replicate fixed randomization designs, which would likely fail to maximize individual participant outcomes.

Second, the time between randomizing a participant into one of the groups and obtaining outcome data must be reasonably quick. Since participants' outcomes influence future participants' randomizations, long periods between randomization and outcome data collection force researchers to either slow recruitment so that previous participants' outcomes can be collected prior to randomizing new participants or randomizing new participants without incorporating data from some of the previously randomized participants.

Logistical Considerations

The randomization ratios in Bayesian adaptive randomization designs can be updated after each participant's outcome data are collected, although this may often be unrealistic. The problem with updating the randomization ratio after collecting each participant's data is that the amount of time, funding, and computational resources needed may not be feasible. For example, collecting a participant's outcome data in the morning prior to a participant's randomization in the afternoon would require dedicating time and effort to entering the outcome data immediately after collecting the data as well as having enough computational power to calculate the updated randomization ratio before the randomization. This also does not address concerns with multisite studies, which would need to maintain a centralized database with participant outcomes and the updated randomization ratio for the study teams at each site when there may be numerous data collections and randomizations happening each day.

To address these issues, block stratification can be used to improve the feasibility of Bayesian adaptive randomization designs. Block stratification is a strategy for updating the adaptive randomization ratio at pre-specified intervals, which might be after every n participants have been randomized or after every n weeks. In practice, this might entail updating the randomization ratio after every 10 participants have been randomized or after every 4 weeks (i.e., monthly).

Data

Bayesian adaptive randomization designs utilize Bayesian data analysis to examine between-group differences in order to adjust the randomization ratio. Therefore, Bayesian adaptive randomization designs incorporate data from the prior distribution and the likelihood to estimate the posterior distribution, which models the probability that one of the treatment groups produces the most favorable outcome.

Prior Distribution

The prior distribution models the *a priori* belief regarding the probability that one of the groups produces the most favorable outcome. For two-group Bayesian adaptive randomization designs, a single prior distribution can fully reflect the probability that each group produces the most favorable outcome, since knowing the probability that one group produces the most favorable outcome allows for the probability the second group produces the most favorable outcome to be calculated. For more complex designs with three or more groups, a prior distribution for each group is needed to estimate the probability that each group produces the most favorable outcome. As is the case in Bayesian data analysis, the prior distribution can be based on the findings of previous studies or on theory. It should be noted, however, that the choice of the prior distribution can bias the findings if the chosen prior distribution is not reflective of the data collected in the study. It should also be noted that the confidence in the prior is reflected by the variance of the prior distribution, and the confidence in the prior impacts how much data in the likelihood are needed to produce findings contrary to the prior.

To give a brief example of how a prior distribution is incorporated into a Bayesian adaptive randomized design, consider a two-group study in which researchers begin with an assumption that the two groups will produce similar outcomes. Because the prior distribution is modeling probabilities, the prior distribution ranges from 0 to 1. Since the researchers believe the two groups will perform similarly, the mode of the prior distribution

is located at 0.50, and the prior distribution is symmetric. Put simply, the mode of the prior distribution implies there is a 50% chance that each group produces the most favorable outcome, and the symmetry of the prior distribution ensures both groups have the same probability of producing the most favorable outcome.

Likelihood

The likelihood models the probability that one of the treatment groups produces the most favorable outcome based on the collected data. As the collected data increase, the variance of the likelihood should decrease, resulting in a more precise estimation of the probability that one of the treatment groups produces the most favorable outcome based on the collected data.

Posterior Distribution

The posterior distribution synthesizes the prior distribution and the likelihood to model the probability that one of the treatment groups produces the most favorable outcome. The mode is often used to generate a point estimate for the probability that one of the treatment groups produces the most favorable outcome. A 95% highest density interval, which includes the 95% of the outcomes that are most likely, is often used to estimate the certainty of the posterior distribution. As more data are collected, the width of the 95% highest density interval often decreases, which reflects a more precise estimate of the probability that one of the treatment groups produces the most favorable outcome.

Early Randomizations

When planning a study using a Bayesian adaptive randomization design, researchers must take special care to plan how the first participants will be randomized. Bayesian adaptive randomization designs use Bayesian data analysis to estimate the probability that each of the groups is producing the most favorable outcome. Consequently, factors impacting the estimation of the posterior distribution may bias the randomization ratio used in a Bayesian adaptive randomization design. Specifically, unstable posterior distributions due to small sample sizes in the early stages of a study are perhaps the largest threat to a Bayesian adaptive randomization design.

There are two primary methods for a study using a Bayesian adaptive randomization design to stabilize the posterior distribution for early randomizations. First, researchers can utilize a burn-in stage, which is defined as a period where the study implements a fixed randomization ratio to allow for a sizable number of

participants to be assigned to all the study groups prior to switching to an adaptive randomization ratio. In practice, this might mean randomizing the first 50 or 100 participants at a 1:1 fixed randomization ratio in a two-group study. Second, researchers can utilize a tuning factor, which weights the obtained outcome data so that studies using a Bayesian adaptive randomized design essentially use a fixed randomization ratio for early randomizations and gradually shift toward an adaptive randomization ratio as more data are collected.

Late Randomizations

In contrast to a fixed randomization design, Bayesian adaptive randomized designs have reduced statistical power because participant allocations and outcomes in Bayesian adaptive randomized designs are correlated. This correlation increases the variance of the outcomes, which makes it harder to distinguish whether there are statistical between-group differences in terms of intervention effectiveness. Hence, more participants are needed in a Bayesian adaptive randomized design to achieve the same level of statistical precision as a fixed randomization design.

To compensate for the reduced statistical power in a Bayesian adaptive randomization design, researchers will often implement early stopping rules. Early stopping rules are defined as a priori conditions for terminating the study based on the magnitude of the probability that one group produces superior outcomes as estimated in the posterior distribution. In practice, researchers may decide to conclude the study if one treatment group has a posterior probability greater than .95 that the treatment is superior to the other treatment(s). It should be noted, however, that there are no defined standards for what constitutes an appropriate early stopping rule. Consequently, the early stopping rules used in practice are variable.

Advantages

Maximizing Individual Participant Outcomes

Bayesian adaptive randomization designs seek to provide the best outcome to each of the individuals participating in the study. Bayesian adaptive randomized designs use empirical evidence regarding the effectiveness of the treatment interventions to adjust the randomization ratio. Consequently, Bayesian adaptive randomized designs are maximizing the likelihood of participants experiencing a positive outcome. At the same time, Bayesian adaptive randomized designs are

minimizing the likelihood of participants experiencing a poor outcome, which is critical in fields such as cancer research.

Incorporating Previous Findings

To better maximize the likelihood of participants experiencing a positive outcome, Bayesian adaptive randomized designs can also incorporate the findings from previous studies. By appropriately incorporating previous findings, the prior distribution used in a Bayesian adaptive randomization design should cause more participants to be allocated into the most effective intervention in the early stages of the study, which should maximize the likelihood of participants experiencing a positive outcome. While there are no guidelines of how similar the previous studies and the current study should be, substantial differences between previous studies and the current study may lead the prior distribution to be a poor reflection of the data collected in the study, which may decrease the likelihood of participants experiencing a positive outcome. Thus, care should be taken in choosing studies to inform the prior distribution.

Limitations

Threats to Internal Validity

Because Bayesian adaptive randomized designs rely on sequential randomization, participants may be differentially affected by threats to internal validity (e.g., history effect, maturation). For example, a study implementing a Bayesian adaptive randomization design for an intervention designed to improve reading comprehension for elementary school students may have reduced internal validity, since the elementary students are experiencing developmental changes during the intervention that could impact the effectiveness of the intervention.

Equally Effective Interventions

Bayesian adaptive randomization designs were created with the intention of maximizing the likelihood of positive outcomes for participants. However, this assumes the superiority of one of the implemented interventions. In studies where there is no superior intervention, the randomization ratio will replicate the fixed randomization ratio used in a traditional randomized design. In such cases, the reduced statistical power of Bayesian adaptive randomization designs dictates that more participants must be randomized to achieve the same level of statistical precision as a fixed randomization design.

Example

Having gone through the characteristics of Bayesian adaptive randomization designs, an example of a study implementing a two-group Bayesian adaptive randomization design will be provided. To preserve the generality of the example for a variety of readers, the interventions will not be described in detail. Rather, they will simply be described as Intervention A and Intervention B, which are associated with Group A and Group B, respectively.

In this hypothetical study, an uninformative prior distribution with a mode of 0.5 will be used, which implies neither intervention is superior. This study will recruit 300 participants, will set the burn-in stage to be 50 participants, will establish an early stopping rule of .95, and will not use block stratification. Of note, this study will use a fixed 1:1 randomization ratio for the 50 participants randomized during the burn-in stage.

When beginning this study, the first 50 participants will be randomized similar to any fixed randomization design, and the outcomes for these 50 participants will be collected. Because the randomization ratio for the first 50 participants is 1:1, there should be approximately 25 participants allocated into each group at this point, although the exact numbers may differ slightly. With approximately 25 participants per group, there should be enough data collected from both groups to obtain stable posterior distribution estimates.

After collecting the outcome data for the 50th randomized participant, the between-group difference in intervention effectiveness is estimated using Bayesian data analysis. For purposes of this example, the process for conducting this Bayesian data analysis will not be presented. Instead, consider the case where there is a 65% chance that Intervention A is more effective than Intervention B, and the randomization ratio adapts to 0.65. Thus, there is a 65% chance the next participant will be allocated into Group A and a 35% chance the next participant will be allocated into Group B.

Continuing the example, the 51st participant is subsequently allocated into Group B, and the outcome for the 51st participant is positive. Consequently, the probability that Group A produces superior outcomes decreases. For the purpose of demonstration, consider the case where there is now a 63% chance that Intervention A is more effective than Intervention B, and the randomization ratio adapts to 0.63. Thus, there is now a 63% chance that the 52nd participant will be randomized into Group A.

Assume the 52nd participant is allocated into Group A, and the outcome for the 52nd participant is positive.

The probability that Group A produces superior outcomes increases. Because more data have been accumulated, the changes in the probability of a group producing a superior outcome, and thus changes in the randomization ratio, will be less with each allocated participant. There is now a 64% chance that Intervention A is more effective than Intervention B, and the randomization ratio adapts to 0.64. Thus, there is now a 64% chance that the 53rd participant will be randomized into Group A.

Continuing the example, the 53rd participant is allocated into Group B, and the outcome for the 53rd participant is negative. Therefore, the probability that Group A produces superior outcomes increases. There is now a 65% chance that Intervention A is more effective than Intervention B, which causes the randomization ratio to adapt to 0.65. Thus, there is now a 65% chance that the 54th participant will be randomized into Group A.

This process will continue with the probability of one group producing superior outcomes being estimated after each participant's data are collected until either (1) the outcome data for the 300th participant is collected or (2) the posterior probability that one of the interventions produces superior outcomes exceeds the early stopping rule of .95.

BAYESIAN DATA ANALYSIS

Bayesian data analysis is an umbrella term that encompasses different data analysis approaches that have in common the use of Bayes's rule as a guiding principle, and the goal of quantifying evidence in favor of possible parameter values, models, or hypotheses, rather than making a decision on whether a parameter value is different than a specific value (e.g., zero) or not. This entry describes two approaches in detail—Bayesian parameter estimation and Bayesian hypothesis testing—and briefly describes two other approaches: Bayesian model comparison and hierarchical Bayesian models.

Bayesian Parameter Estimation

The goal of Bayesian parameter estimation is the same as the traditional frequentist parameter estimation: to make an estimation of the value of a population parameter such as a mean, a difference between two means, a correlation between two variables, or a regression coefficient. The difference between the two approaches is that in the traditional approach the estimation consists of providing a point estimate and a confidence interval, typically a 95% confidence interval, whereas in the Bayesian approach the estimation consists of providing a posterior distribution, which could be summarized, for instance, with the mean of the distribution and its 2.5th and the 97.5th percentiles (i.e., a 95% credible interval or the 95% high-density interval).

The advantage of the 95% credible (or high density) interval in Bayesian parameter estimation is that it provides the information that researchers are typically interested in. It indicates that the probability that the actual value of the parameter of interest (e.g., the population mean of a variable) is within the interval is 95%. In other words, the researcher can be 95% confident that the actual parameter value is in the interval. The traditional 95% confidence interval is more difficult to interpret: It is the interval generated by a procedure that provides confidence intervals that include the actual parameter value 95% of the times the procedure is used. The process to obtain a posterior distribution of a parameter of interest consists of four steps: choice of

distribution to create the likelihood function, choice of prior distribution, data collection and obtention of relevant statistics, and obtention of posterior distribution.

Choice of Distribution to Create the Likelihood Function

Let's consider the case in which a researcher aims to estimate the proportion of people who are currently experiencing anxiety in a specific city by administering an anxiety scale to 200 people in that city; that scale determines whether the person is experiencing anxiety (1) or not (0). The distribution to create the likelihood function has a resemblance with the sampling distribution in the traditional approach. In this case, the binomial distribution is the most appropriate distribution to construct the likelihood function. The binomial distribution provides the probability of obtaining a specific number of people with anxiety in the sample of 200 participants given that the proportion of people of anxiety in the population (denoted by π) is a determined value. For example, if $\pi = 0.50$, the most probable value in the sample is 100 people with anxiety, while 99 and 101 being the second most probable values, 98 and 102 following in probability, and so forth, with values close to 0 and 200 having an extremely low probability of occurrence. The binomial distribution is then used to construct a likelihood function over parameter values once the data are observed. The likelihood function will come into play again when this function is combined with the prior distribution to produce the posterior distribution.

Choice of Prior Distribution

In Bayesian parameter estimation, the prior distribution is the credibility for each possible parameter value given by a researcher before observing new data. The researcher declares what credibility they give to each possible parameter value by using a probability distribution. This distribution is known as the *prior distribution* (or just *the prior*). That is, the Bayesian researcher makes explicit their knowledge about the parameter values before collecting the data. There are two main approaches to choose the prior distribution. In the first approach, the researcher declares to be ignorant regarding the possible parameter values, and this ignorance is expressed by choosing a probability distribution in which all the possible parameter values are equally likely. Given that π can be any value between 0 and 1, a continuous uniform distribution with range 0 to 1 would be appropriate. However, for reasons that will be clear later, a beta distribution is typically used for proportions. A beta distribution with parameters $\alpha = 1$ and $\beta = 1$ is equivalent to the continuous uniform distribution

over the range 0 to 1. This type of prior distribution is typically called *uninformed prior*.

In the second approach, the researcher uses their actual knowledge of the parameter values and expresses it in the prior distribution. Suppose the researcher knows of a previous study measuring anxiety in the same city with 50 participants, in which 20 of them had anxiety and 30 did not have anxiety. They can express this knowledge with a beta prior distribution with parameters $\alpha = 20$ and $\beta = 30$. In that distribution the most probable value is 0.40, and the lower bound and upper bound of the 95% credible interval of the distributions are 0.27 and 0.58, respectively. This type of prior distribution is typically referred to as *informed prior*.

Data Collection and Obtention of Relevant Statistic

Once the binomial distribution is chosen to construct the likelihood function and the beta distribution is chosen as prior distribution, it is time to collect the data (in this case, the administration of an anxiety scale to 200 participants) and obtain the value of the statistic of interest, that is, the number of people with anxiety. Assume that the results indicate that 40 participants have anxiety and 160 participants do not have anxiety.

Obtention of Posterior Distribution

The posterior distribution is obtained by using the Bayes's rule as guiding principle:

$$P(\theta|d) = \frac{P(d|\theta) \times P(\theta)}{P(d)},$$

which in English can be expressed as:

$$\text{Posterior distribution} = \frac{\text{Likelihood} \times \text{Prior distribution}}{\text{Marginal likelihood}},$$

where θ denotes any parameter value in a generic way. When referring to specific parameters, a different Greek letter takes the place of θ . For example, π is used for population proportions, μ is used for population means, σ is used for population standard deviations, ρ is used for population correlation, and β is used for population regression slopes. In this case, θ represents the proportion of persons with anxiety in the population; thus, in this explanation π and θ are used interchangeably. Note that we do not know the actual value of θ , so we must consider all the possible values between 0 and 1. $P(\theta)$ is the prior distribution, which in the example is either a beta distribution with parameters $\alpha = 1$ and $\beta = 1$ for the uninformed prior or a beta distribution with parameter $\alpha = 20$ and parameter $\beta = 30$

for the informed prior. $P(d|\theta)$ is the probability of the observed data (d) given each possible parameter value, also known as the *likelihood of the possible parameter values*. Some authors use the notation $L(\theta|d)$, which is very useful because it identifies that, as the prior and posterior distributions, we are dealing with a function that assigns a number to all the possible parameter values. It is not strictly a probability distribution because it does not add to 1 as discrete probability distributions do or it does not integrate to 1 as continuous probability distributions do. However, it works as a probability distribution in the sense that somehow indicates how likely each parameter value is.

The construction of the likelihood function is rather artificial; here is an example to explain the process. After observing that the data are 40 people with anxiety out of 200, we use the binomial distribution to determine the probability of obtaining 40 successful outcomes out of 200 trials for all possible values of π . For clarity of explanation, only four possible values of π are considered, but it should be considered that π can acquire infinite number of values in the range 0 to 1. (Note that we are now using as π instead of θ .)

$$L(\pi = 0.15|d = 40) = P(d = 40|\pi = 0.15) = 0.0115$$

$$L(\pi = 0.20|d = 40) = P(d = 40|\pi = 0.20) = 0.0704$$

$$L(\pi = 0.25|d = 40) = P(d = 40|\pi = 0.25) = 0.0173$$

$$L(\pi = 0.30|d = 40) = P(d = 40|\pi = 0.30) = 0.0041$$

The first line should be interpreted as the likelihood of the parameter π to be the value 0.15 in the population (i.e., the city of interest) given that we observed 40 out of 200 people with anxiety in the sample. This is calculated by using the binomial distribution and determining the probability of observing 40 out of 200 successes given that the probability of success in each trial (i.e., π) is 0.15. That probability is 0.0115. The second line indicates how likely is for π to be 0.20, the third how likely is for π to be 0.25, and the fourth line indicates how likely is for π to be 0.30. In this set of values, the most likely value is 0.20 with a probability of 0.0704. We can keep adding parameter values in the range 0 to 1 and obtaining the likelihood for each of them, and eventually we will obtain a function that resembles a probability distribution.

To calculate the posterior distribution, we need to follow three more steps. The first one is to follow the numerator of Bayes's rule and, for each parameter value, to obtain the product of its likelihood and its prior probability. This new set of values gives us a good idea of the plausibility of each parameter value after

observing the data and taking into account previous knowledge; however, it is not a probability distribution because it does not add or integrate to 1. We can obtain a proper posterior distribution if there is a way of calculating the marginal likelihood [i.e., $P(d)$], which is a single number obtained with the following integral:

$$\int_{\theta} P(d|\theta) \times P(\theta) d\theta,$$

where the d in $d\theta$ does not refer to data, rather it indicates the integration is over all possible values of θ . Calculating this integral is not always feasible, and when this is the case, Monte Carlo simulation methods are used to approximate it, methods that are explained in this entry. In this example, the choice of the beta distribution as prior and the binomial distribution for constructing the likelihood was not coincidental. These two distributions have the property of conjunction, which means that there is a way of combining them to easily come up with a new probability distribution. When conjunction is possible, the posterior distribution can be obtained without calculating the marginal likelihood.

For the uninformed prior, the beta distribution with $\alpha = 1$ and $\beta = 1$ combined with the binomial with 40 success (and 160 failures), the posterior distribution is a beta distribution with $\alpha = 41$ ($40 + 1$) and $\beta = 161$ ($160 + 1$). In this case, the posterior distribution has exactly the same shape as the likelihood function, which makes sense because the prior represented the ignorance of the researcher, thus the information about the parameter value in the posterior distribution is entirely provided by the new observed data, which is captured by the likelihood function. For the informed prior, the posterior distribution becomes a beta distribution with $\alpha = 60$ ($40 + 20$) and $\beta = 190$ ($160 + 30$). In this posterior distribution, the mean is 0.24 and the 95% high-density interval is (0.189, 0.295). Note that the prior probability distribution was centered on 0.40 and that the likelihood was centered on 0.20 and the posterior distribution is centered on 0.24. The center of the posterior distribution is closer to that of the likelihood than that of the prior because the prior only incorporated knowledge of a sample of 50 participants, whereas the likelihood provided information over 200 participants; therefore, the latter has more weighting in the posterior distribution.

Practical Issues

Bayesian parameter estimation forms part of all the other approaches, but John Kruschke has been a strong proponent of Bayesian parameter estimation as a

stand-alone procedure. Kruschke's website (<https://jkkweb.sitehost.iu.edu/index.html>) provides a number of useful resources for conducting parameter estimation. The R packages `rstan` and `rjags` afford the possibility to conduct Bayesian parameter estimation with limited coding knowledge. The user friendly and free software JASP was built with the purpose of conducting Bayesian hypothesis testing, but it also provides posterior distributions with credible intervals.

Bayesian Hypothesis Testing

Bayesian hypothesis testing is an approach to compare a null hypothesis with an alternative hypothesis. There are a few differences between the Bayesian and the traditional hypothesis testing approaches. First, in the Bayesian approach, there is a model for the null hypothesis and a model for the alternative hypothesis, unlike the traditional approach in which only a model for the null hypothesis is specified. This allows the Bayesian approach to quantify the evidence in favor or against the alternative hypothesis relative to the null hypothesis and vice versa. Second, the Bayesian approach uses Bayes factors, not p values as in the traditional approach. Third, the Bayes factor quantifies the relative evidence in favor or against the hypotheses, it does not make a binary decision (reject or not reject) regarding the null hypothesis.

The process for conducting Bayesian hypothesis testing involves specifying two models and comparing them. Let's consider a case in which a t -test is used in the traditional approach. A sample of 80 participants was randomly allocated to two conditions to perform a memory task: fast presentation of stimulus (40 participants) or slow presentation of stimulus (40 participants). The mean percentage of correct answers was obtained for each group, and the goal of the study was to test the null hypothesis that there are no differences in performance in this memory task between the two groups. The mean percentage items correctly recalled in the group that was presented stimuli at a fast pace was 50.15 and $SD = 16.4$ and that of the group that was presented stimuli at a slow pace was 61.18, $SD = 15.2$. The mean difference is -11.03 . The pooled SD is 15.8; therefore, the effect size in the sample is: $-11.03/15.8 = -0.698$.

Specification of Priors Over Parameter Values and Models

In Bayesian parameter estimation, one only considers one model at a time, whereas in Bayesian null hypothesis testing, two models are compared. One must both specify a prior distribution over parameter

values for each of the models and also specify the prior distribution over the models.

Regarding the prior distribution of parameters, the parameter of interest is the difference between means in memory performance in a hypothetical population of people exposed to slow presentation of stimuli compared to one in which people are exposed to fast presentation of stimuli. For practical reasons, a standardized effect size is used for this parameter, and it is denoted by δ , which is calculated by $\delta = \text{difference between population means} / \text{combined standard deviation in the population}$.

The prior distribution over the possible parameter values for the model of the null hypothesis is:

$$H0 : \delta = 0.$$

This means that for the model of the null hypothesis, the whole probability is given to the parameter value 0, values different than 0 are impossible, and are given a probability of 0. For the alternative hypothesis, there are many options for prior distribution. In this example, we will use a normal distribution centered on 0.

$$H1 : \delta \sim \text{Normal} (\pi = 0, \sigma = 1).$$

In this model of the alternative hypothesis, the prior distribution for the difference between means gives the value 0 the highest probability, given that the mean (π) of a normal distribution is its most probable value, and values higher and smaller than 0 that are close to 0 are highly probable whereas values far away from zero are less probable. The spread of the normal distribution is determined by its standard deviation (σ). There is an extensive literature on determining default values for parameters such as σ , which will not be discussed here. Suffice it to say that in experimental research in social sciences, large differences between means are unlikely, so the default value of σ should reflect this fact; in this case, $\sigma = 1$ was chosen. If the researcher has the knowledge or expectation that one of the groups will have higher performance than the other group, they may express that by using a half-normal distribution, that is, a normal distribution centered on 0, but with the left side of the distribution removed, making explicit the assumption that the value of δ in the population is higher than zero. This is equivalent to a directional hypothesis in traditional null hypothesis testing.

Regarding the prior distribution over models, the default distribution is the following:

$$P(H0) = 0.5, P(H1) = 0.5.$$

This uniform distribution is equivalent to the uninformed prior explained in the parameter estimation section. In this case, the researcher makes explicit that they do not have previous knowledge on which hypothesis is more plausible or they prefer not to use any previous knowledge for hypothesis testing. There are situations in which a researcher may decide to be conservative and assign H_0 a higher prior probability than that for H_1 . For example, if H_1 involves showing that telepathy exists, because it involves violating well established laws of physics, a researcher may assign a lower prior probability to H_1 and only favor H_1 over H_0 if the data provide extraordinary evidence in favor of H_1 .

Specification of Likelihood

The specification of likelihood over parameter values is the same as in Bayesian parameter estimation. Again, there are a few distributions that can be used to construct the likelihood such as a t distribution centered on any possible parameter value. For simplicity, assume a normal distribution. The rationale is the following: If in the population $\delta = 0$, in the sample used in the study one would expect the difference in memory performance between the two groups to be 0 or close to 0, with values far away from 0 being very unlikely. Likewise, if $\delta = 8.5$, then one would expect the difference between means in the sample to be 8.5 or values close to 8.5, with values far from 8.5 being very implausible. Please refer to the likelihood in Bayesian parameter estimation to see how the likelihood is constructed after this step.

Bayes's Rule

In hypothesis testing, we need to use two versions of Bayes's rule. First, a version with a posterior distribution over parameter δ :

$$H_0: P(\delta|d, H_0) = \frac{P(d|\delta, H_0) \times P(\delta|H_0)}{P(d|H_0)} \times P(H_0),$$

$$H_1: P(\delta|d, H_1) = \frac{P(d|\delta, H_1) \times P(\delta|H_1)}{P(d|H_1)} \times P(H_1),$$

where $P(H_0) = P(H_1) = 0.5$ are the priors for the hypotheses, $P(\delta|H_0)$ is the prior of δ for the null hypothesis (i.e., $\delta = 0$), $P(\delta|H_1)$ is the prior of δ for the alternative hypothesis (i.e., a normal distribution with $\mu = 0$ and $\sigma = 1$), and $P(d|\delta, H_0)$ and $P(d|\delta, H_1)$ denote the likelihoods over parameter values for the models of the null and the alternative hypotheses, which in both cases are obtained via a normal distribution.

Given that the observed standardized difference between means in our sample of 80 participants is -0.698 , the likelihood in the model of the null hypothesis is the probability of observing that value given that $\delta = 0$, whereas in the model of the alternative hypothesis the likelihood includes the probability of observing -0.698 , given all possible values of δ . As in parameter estimation, the marginal likelihoods $P(d|H_0)$ and $P(d|H_1)$ are calculated with the integrals

$$\int_{\delta} P(d|\delta, H_0) \times P(\delta|H_0) d\delta$$

and

$$\int_{\delta} P(d|\delta, H_1) \times P(\delta|H_1) d\delta,$$

respectively.

The second version of Bayes's rule contains a posterior over models, not parameter values, denoted by the following equations:

$$P(H_0|d) = \frac{P(d|H_0)}{P(d)} \times P(H_0),$$

$$P(H_1|d) = \frac{P(d|H_1)}{P(d)} \times P(H_1).$$

These versions of the Bayes's rule show the posterior of the models for the null and the alternative hypotheses, which are calculated with the likelihood of the hypothesis given the data [$L(H_0|d) = P(d|H_0)$ and $L(H_1|d) = P(d|H_1)$, respectively], the priors of the hypotheses [$P(H_0)$ and $P(H_1)$, respectively], and the probability of the data [$P(d)$]. Note that the likelihoods in this version of the Bayes's rule are equivalent to the marginal likelihoods in the previous version, and they denote how plausible is the observed effect size of -0.698 given the prior distribution assigned over δ in each model. In the current version, the probability of the data $P(d)$ represents how plausible is to observe -0.698 , for a model that combines the model of H_0 and the model of H_1 .

Bayes Factor

The Bayes factor is a ratio. In this instance, the ratio between the marginal likelihood under the model of the null hypothesis and the marginal likelihood under the model of the alternative hypothesis. Obtain the Bayes factor by obtaining the ratio of the two previous equations:

$$\frac{P(H_0|d)}{P(H_1|d)} = \frac{P(d|H_0) \times P(H_0) / P(d)}{P(d|H_1) \times P(H_1) / P(d)},$$

The probability of the data $P(d)$ is the same value for both models; therefore, this value can be simplified from the equation and obtain:

$$\frac{P(H0|d)}{P(H1|d)} = \frac{P(d|H0)}{P(d|H1)} \times \frac{P(H0)}{P(H1)}$$

which can be expressed in English as:

Posterior odds = Bayes factor $\times$ Prior odds

$$\text{That is, Bayes factor} = \frac{P(d|H0)}{P(d|H1)}.$$

The Bayes factor must be interpreted as how plausible the data are under a model (i.e., the model of the null hypothesis) relative to how plausible the data are under another model (i.e., the model of the alternative hypothesis). This ratio is named as Bayes factor 01. Using JASP, the Bayes factor 01 returns the value 0.0574. When the Bayes factor 01 is a number below 1, it is more useful to calculate the Bayes factor 10, that is, the ratio between the marginal likelihood of the model of the alternative hypothesis and that of the model of the null hypothesis. Alternatively, the same value can be achieved by Bayes factor 10 = 1/Bayes factor 01. The corresponding value is 17.4245, indicating that the data are more than 17 times more likely under the alternative hypothesis than under the null hypothesis. This quantification of the evidence in favor of the alternative hypothesis relative to the null hypothesis is the end of the analysis, unlike in the traditional approach in which a binary decision on whether to reject the null hypothesis is carried out.

Practical Issues

The use of Bayes factor to evaluate hypotheses was introduced by Robert E. Kass and Adrian E. Raftery in 1995. More recently, it has been popularized by psychologist Eric-Jan Wagenmakers, who has been developing a free and easy to use statistical software, JASP, with emphasis on Bayesian hypothesis testing, which can be downloaded for free from jasp-stats.org. This software builds on the work of other researchers, who developed default priors to test null hypotheses via Bayes factor to replace traditional tests such as t test, analysis of variance, regression, correlation, binomial test, and chi-squared test, among others.

Other Bayesian Approaches

Another important approach is Bayesian model comparison. The Bayesian model comparison approach also uses Bayes factor, but instead of comparing a null

hypothesis with an alternative hypothesis, it compares any two models that aim at explaining the data. Model comparison can occur between nested models, such as a regression model with one intercept and one slope compared to a regression model with those parameters plus an additional slope parameter, and non-nested models such as one that explains the outcome variable with one predictor variable with another that does so with a completely different predictor variable. Models that have the same predictor variables but differ in the function that relates the predictor variable with the outcome variables can also be compared, such as a linear model with a quadratic model. Finally, an interesting feature of the Bayesian model comparison approach is that it can compare models that have the same predictor variables and functions linking them to the outcome variables but differ in their prior probability distribution for possible parameter values. Andrew Gelman has introduced these models to social sciences, and Richard McElreath's book, *Statistical Rethinking*, presents multiple examples of this approach in a didactic way.

The final approach is hierarchical Bayesian models. These models possess multiple prior distributions and at different levels; they have characteristics of traditional structural equation models because they have multiple variables and pathways connecting them, multilevel models because they have parameters at different levels (e.g., a parameter can vary among individuals or it is fixed for all the individuals, another may vary or be fixed among trials, and so forth), and directed acyclical graphs because they share the graphical representation with those models. An innovative feature of hierarchical Bayesian models is the use of plates, a graphical device to represent whether a parameter is fixed or varies among individuals, trials, or time, for example.

Final Thoughts

Bayesian data analysis approaches, as indicated earlier, share the use of Bayes's rule as a guiding principle for data analysis. They also share another unique feature: They explicitly manifest the knowledge the researcher has before observing new data, and that knowledge is updated after observing new data. This feature dovetails with the cumulative and collaborative nature of the scientific endeavor. Strong conclusions based on single studies are discouraged and the cumulative quantification of evidence is encouraged.

BAYESIAN INFORMATION CRITERION

Bayesian (or Bayes) information criterion (BIC), also referred to as *Schwarz Bayes information criterion*, is one of the information criteria for selecting statistical models. BIC, as its name tells, is based on the asymptotic behavior of Bayes estimators under a class of priors. It is defined mathematically as $L2 - r \log(N)$, in which N is the total sample size and r is the number of degrees of freedom after model fitting.

History of BIC

BIC was first proposed by Gideon E. Schwarz in his 1978 paper, “Estimating the Dimension of a Model,” published in the *Annals of Statistics*, based on a Bayesian approach to hypothesis testing developed by Harold Jeffreys in 1961. According to Schwarz, using the maximum likelihood principle to choose the appropriate model is problematic because this principle results in the highest possible dimension rather than the right dimension. The approach based on Bayes estimator assumes that observations are relative to some fixed measure on the sample space with some density. When the asymptotes of Bayes are fitted, researchers need not know the specification of a priori distribution on the parameters. Furthermore, it is assumed that there is a fixed penalty for estimating the wrong model, regardless of the sample size, because the Bayes solution selects a most probable a posteriori model based on the a priori distribution.

Therefore, a model is considered true when it has the highest posterior probability, without specifying a prior distribution.

Although Schwartz was the first person who proposed BIC, his work was not paid attention to until Adrian E. Raftery used the BIC in a wide range of models and strongly advocated for its usefulness in his two papers published in 1986: one was “Choosing Models for Cross-Classifications” in *American Sociological Review* and the other was “A Note on Bayes Factors for Log-linear Contingency Table Models With Vague Prior Information” in *Journal of the Royal Statistical Society*. He argued that the Bayesian approach is better for hypothesis testing especially with a larger sample size and it can also account for model uncertainty with the use of priors.

Variants of BIC

Besides the original form of BIC, there are other revised forms or variants of BIC, including Kashyap Bayesian information criterion (KBIC) developed by Rangasami L. Kashyap in 1982, adjusted Bayesian information criterion (ABIC) developed by Stanley L. Sclove in 1987, the Houghton Bayesian information criterion (HBIC) developed by Dominique M. A. Houghton in 1988, the distributed Bayesian information criterion (DBIC) developed by David Draper in 1995, as well as the information matrix-based Bayesian information criterion (IBIC) and the scaled unit information proper Bayesian information criterion (SPBIC) developed by Kenneth A. Bollen and colleagues in 2012.

More specifically, KBIC selects a time-series model in BIC equation. ABIC focuses on the shortest description length in model selection and keeps a balance between model fit and complexity. It is also known as the *sample-size-adjusted BIC*. HBIC extends BIC’s focus on linear models to curve models and reduces the penalty in BIC. DBIC adds a term to BIC equation that has better results with small to moderate sample sizes. IBIC adds two terms into the original equation of BIC, and SPBIC uses scaled unit information prior rather than unit information prior in the original form of BIC.

Use of BIC

BIC is used as a criterion of model selection and can be applied in many models, such as log linear, logits, covariance structure models, and linear regression. It includes an adjustment for sample size and has consistency property, which suggests that, when sample size increases and approaches infinity, the BIC selects the fitted mode with probability close to 1. This makes BIC useful

especially when researchers are building theories based on data because they assume that they can collect data, fit the model based on BIC, and select the true model as the sample size increases. Researchers need to compute the BIC for each model and select the model with the smallest criterion value. In this sense, BIC focuses on parsimony of the model.

Although BIC and other information criterion measures are not used as popularly as other fit indices in fields such as structural equation modeling (SEM), they outperform other fit indices in moderate to large samples and in models that have extra parameters. When the SEM model includes real-world criterion, or criterion that is measurable, BIC is probably the most effective for model accuracy and parsimony. Among variants of BIC, ABIC has a better performance than original BIC in selecting numbers of factors and latent classes. DBIC has an improved performance in model selection for real problems. HBIC improves BIC's performance particularly in confirmatory factor analysis models. It, along with SPBIC, performs the best in the selection of true models and has the highest accuracy ratios in model fitting.

Limitations of BIC

Despite its overall superior performance in model selection, BIC has its own limitations. For instance, because Bayes factors are sensitive to differences existing in prior beliefs, they are not always the same as the Bayes factor implied by prior beliefs. Furthermore, the advantages of including total sample size in the BIC makes it harder to discriminate between null and alternative hypotheses based only on sample size. When testing the difference between two group means, a sample of 1,000 participants in each group is more informative than a sample of 200 participants in one group and 1,800 in the other. Because the BIC uses the total sample size in the study, the difference between the samples in the two situations is not obvious and the use of prior beliefs in the BIC is difficult to justify. In addition, BIC seems too conservative in model selection.

BAYESIAN NETWORKS

Bayesian networks are probabilistic graphical models depicting the relations within a potentially large set of variables. Commonly, Bayesian networks show the conditional dependencies, information that cannot easily be derived from, for example, a correlation table. Thus, these networks are a versatile tool for exploring and studying relations in large data sets and are used in many branches of science.

Graphical Model

In its essence, Bayesian network models are graphical visualizations of variables and their relations, whereby the values of their relations depend on random variation. Just as in structural equation models and factor models, for example, these visualizations show each variable as an ellipse, called a *node*, and the relations are depicted by arrows, called *edges* or *ties*, between variables.

The graph satisfies the formal requirements of Bayesian networks if it is a so-called directed acyclic graph (DAG). In a directed graph, all connections are arrows—usually indicating causal relations—and there are no cycles in the graph. No cycles implies that if there is a directed path from node A to node B, there cannot be a path from node B to node A.

Many studies focus on correlational relations rather than causal relations. A variant of the Bayesian networks, where directed arrows are replaced by undirected lines, is useful in this context. Although technically not a Bayesian network, these graphs are also commonly referred to as *Bayesian networks*.

Figure 1 displays the Bayesian network for a fictitious example. For 300 primary school children, three variables are recorded: age (X_1), their shoe size (X_2), and their numeracy level, based on some arithmetic test (X_3). These nodes are depicted as ellipses, with the relations as arrows. In this example, the direction of the

Figure 1 Example of a Bayesian Network

causal arrows is clear: one's feet grow with age, and so does one's arithmetic skills.

Perhaps the most interesting thing about Figure 1 is the lack of edge between X_2 and X_3 . This does not imply that these two variables are unrelated. In fact, they are probably strongly correlated: kids with large feet tend to also be the kids with better arithmetic skills, as these children are the older ones in the sample. Variables X_2 and X_3 have no edge as these are *conditionally independent*: given the value for X_1 , the two variables are unrelated. In other words, for children of the same age, there is no relation between shoe size and numeracy.

Formally, variables A and B are independent conditional on variables $C_1, \dots, C_k$ if

$$P(A \cap B | C_1, \dots, C_k) = P(A | C_1, \dots, C_k) \times P(B | C_1, \dots, C_k).$$

As this notation relies on conditional probabilities, Bayes's theorem is required, hence the name Bayesian network. The notation for this is $A \perp\!\!\!\perp B | C_1, \dots, C_k$. The conditional independence property of DAGs is what makes the Bayesian network so useful in practice. This is especially the case when working with a large number of variables. By conditioning on certain nodes, sets of other nodes can become independent, which is of great help in interpreting the results.

Gaussian Graphical Model

A common type of Bayesian network model is the Gaussian graphical model (GGM). This model assumes that the joint distribution of all variables is multivariate normal: $X \sim N(\mu, \Sigma)$. In this case, the inverse of the variance/covariance matrix Σ immediately provides the values for the edges of the network. Where Σ itself is used to compute the correlations between variables, Σ^{-1} is used to compute the so-called partial correlations. The normality assumption of the GGM can be checked in a similar way as checking this assumption for standard linear regression models.

There are two methods for visualizing the edges of a graph: (1) lines and arrows are either present or absent,

denoting the presence or absence of a relation, or (2) lines and arrows vary in thickness, denoting the strength of the relation, with another property (different line color or using dashed lines) to indicate when relations are negative. As partial correlations in practice never are exactly zero, raw visualizations of a GGM can yield visual overload: when all edges are drawn, it is difficult to assess where the interesting edges are. A straightforward solution to this is called *thresholding*: visualize only those partial correlations that, in absolute value, exceed some threshold (e.g., 0.2). Correlations smaller than this threshold are deemed to be of too little interest. More sophisticated solutions, such as the graphical lasso, might provide a more elegant graph.

Bayesian Networks in the Social Sciences

Within the social sciences, Bayesian networks occur in two classes: social networks and psychological networks. In social network analysis, the nodes represent entities, such as Facebook users, and the edges represent 0/1 variables, such as indicating whether or not two Facebook users are (mutual) friends. The interest does not lie in specific individuals in the network but on the behavior of the network as a whole. Relevant concepts in this field include density (how many edges are there, relative to the possible number of edges) and centrality (which nodes are most connected, who are the key influencers).

Psychological network analysis has a different focus. Here, the nodes concern psychological variables, such as symptoms of anxiety disorder, and the edges represent the partial correlations. Thus, the values of the edges are now realizations of a random process, rather than observed 0/1 scores. One of the main aims in this branch of network analysis is to find pathways connecting one symptom to another. By intervening on one of the symptoms on this path, and thus keeping this constant, one hopes to avoid having other symptoms worsen.

Especially thanks to recent innovations in software for network analysis, the use of network models has increased rapidly since the first decade of the 21st century.

BEHAVIOR ANALYSIS DESIGN

Behavior analysis is a specific scientific approach to studying behavior that evolved from John Watson's behaviorism and the operant research model popularized by B. F. Skinner during the middle of the 20th century. This approach stresses direct experimentation and measurement of observable behavior. A basic assumption of behavior analysis is that behavior is malleable and controlled primarily by consequences. B. F. Skinner described the basic unit of behavior as an *operant*, a behavior emitted to operate on the environment. Additionally, he proposed that the response rate of the operant serve as the basic datum of the scientific study of behavior. An operant is characterized by a response that occurs within a specific environment and produces a specific consequence. According to the principles of operant conditioning, behavior is a function of three interactive components, illustrated by the three-term contingency: context, response, and consequences of behavior. The relationship between these three variables forms the basis of all behavioral research. Within this framework, individual components of the three-term contingency can be studied by manipulating experimental context, response requirements, or consequences of behavior. A change in any one of these components often changes the overall function of behavior, resulting in a change in future behavior. If the consequence strengthens future behavior, the process is called *reinforcement*. If future behavior is weakened or eliminated as a result of

changing the consequence of behavior, the process is called *punishment*.

Behavior analysis encompasses two types of research: the experimental analysis of behavior, consisting of research to discover basic underlying behavioral principles, and applied behavior analysis, involving research implementing basic principles in real-world situations. Researchers in this field are often referred to as behavior analysts, and their research can take place in both laboratory and naturalistic settings and with animals and humans. Basic behavioral processes can be studied in any species, and the findings may be applied to other species. Therefore, researchers can use animals for experimentation, which can increase experimental control by eliminating or reducing confounding variables. Since it is important to verify that findings generalize across species, experiments are often replicated with other animals and with humans. Applied behavior analysis strives to develop empirically based interventions rooted in principles discovered through basic research. Many empirically based treatments have been developed with participants ranging from children with autism to corporate executives and to students and substance abusers. Contributions have been made in developmental disabilities, intellectual developmental disorders, rehabilitation, delinquency, mental health, counseling, education and teaching, business and industry, and substance abuse and addiction, with potential in many other areas of social significance. Similar designs are employed in both basic and applied research, but they differ with regard to subjects studied, experimental settings, and degree of environmental control.

Regardless of the subject matter, a primary feature of behavior analytic research is that the behavior of individual organisms is examined under conditions that are rigorously controlled. One subject can provide a representative sample, and studying an individual subject thoroughly can sometimes provide more information than can studying many subjects because each subject's data are considered an independent replication. Behavior analysts demonstrate the reliable manipulation of behavior by changing the environment. Manipulating the environment allows researchers to discover the relationships between behavior and environment. This method is referred to as *single-subject* or *within-subject research* and requires unique designs, which have been outlined by James Johnston and Hank Pennypacker. Consequently, this method takes an approach to the collection, validity, analysis, and generality of data that is different from approaches that primarily use group designs and inferential statistics to study behavior.

Measurement Considerations

Defining Response Classes

Measurement in single-subject design is objective and restricted to observable phenomena. Measurement considerations can contribute to behavioral variability that can obscure experimental effects, so care must be taken to avoid potential confounding variables. Measurement focuses on targeting a *response class*, which is any set of responses that result in the same environmental change. Response classes are typically defined by function rather than topography. This means that the form of the responses may vary considerably but produce the same result. For example, a button can be pressed several ways, with one finger, with the palm, with the toe, or with several fingers. The exact method of action is unimportant, but any behavior resulting in button depression is part of a response class. Topographical definitions are likely to result in classes that include some or all of several functional response classes, which can produce unwanted variability. Researchers try to arrange the environment to minimize variability within a clearly defined response class.

There are many ways to quantify the occurrence of a response class member. The characteristics of the behavior captured in its definition must suit the needs of the experiment, be able to address the experimental question, and meet practical limits for observation. In animal studies, a response is typically defined as the closing of a circuit in an experimental chamber by depressing a lever or pushing a key or button. With this type of response, the frequency and duration that a circuit is closed can be recorded. Conditions can be arranged to measure the force used to push the button or lever, the amount of time that occurs between responses, and the latency and accuracy of responding in relation to some experimentally arranged stimulus. These measurements serve as dependent variables. In human studies, the response is typically more broadly defined and may be highly individualized. For example, self-injurious behavior in a child with autism may include many forms that meet a common definition of minimum force that leaves a mark. Just as in basic research, a variety of behavioral measurements can be used as dependent variables. The response class must be sensitive to the influence of the independent variable (IV) without being affected by extraneous variables so that effects can be detected. The response class must be defined in such a way that researchers can clearly observe and record behavior.

Observation and Recording

Once researchers define a response class, the methods of observation and recording are important in order to obtain a complete and accurate record of the subject's behavior. Measurement is direct when the focus of the experiment is the same as the phenomenon being measured. Indirect measurement is typically avoided in behavioral research because it undermines experimental control. Mechanical, electrical, or electronic devices can be used to record responses, or human observers can be selected and trained for data collection. Machine and human observations may be used together throughout an experiment. Behavior is continuous, so observational procedures must be designed to detect and record each response within the targeted response class.

Experimental Design and Demonstration of Experimental Effects

Experimental Arrangements

The most basic single-subject experimental design is the baseline–treatment sequence, the AB design. This procedure cannot account for certain confounds, such as maturation, environmental history, or unknown extraneous variables. Replicating components of the AB design provide additional evidence that the IV is the source of any change in the dependent measure. Replication designs consist of a *baseline* or *control* condition (A), followed by one or more *experimental* or *treatment* conditions (B), with additional conditions indicated by successive letters. Subjects experience both the control and the experimental conditions, often in sequence and perhaps more than once. An ABA design replicates the original baseline, while an ABAB design replicates the baseline and the experimental conditions, allowing researchers to infer causal relationships between variables. These designs can be compared with a light switch. The first time one moves the switch from the on position to the off position, one cannot be completely certain that one's behavior was responsible for the change in lighting conditions. One cannot be sure the light bulb did not burn out at that exact moment or the electricity did not shut off coincidentally. Confidence is bolstered when one pushes the switch back to the on position and the lights turn back on. With a replication of moving the switch to off again, one has total confidence that the switch is controlling the light.

Single-subject research determines the effectiveness of the IV by eliminating or holding constant any potential confounding sources of variability. One or more behavioral measures are used as dependent variables so

that data comparisons are made from one condition to another. Any change in behavior between the control and the experimental conditions is attributed to the effects of the IV. The outcome provides a detailed interpretation of the effects of an IV on the behavior of the subject.

Replication designs work only in cases in which effects are reversible. Sequence effects can occur when experience in one experimental condition affects a subject's behavior in subsequent conditions. The researcher must be careful to ensure consistent experimental conditions over replications. Multiple-baseline designs with multiple individuals, multiple behaviors, or multiple settings can be used in circumstances in which sequence effects occur, or as a variation on the AB design. Results are compared across control and experimental conditions, and factors such as irreversibility of effects, maturation of the subject, and sequence effect can be examined.

Behavioral Variability

Variability in single-subject design refers both to variations in features of responding within a single response class and to variations in summary measures of that class, which researchers may be examining across sessions or entire phases of the experiment. The causes of variability can often be identified and systematically evaluated. Behavior analysts have demonstrated that frequently changing the environment results in greater degrees of variability. Inversely, holding the environment constant for a time allows behavior to stabilize and minimizes variability. Murray Sidman has offered several suggestions for decreasing variability, including strengthening the variables that directly maintain the behavior of interest, such as increasing deprivation, increasing the intensity of the consequences, making stimuli more detectable, or providing feedback to the subject. If these changes do not immediately affect variability, it could be that behavior requires exposure to the condition for a longer duration. Employing these strategies to control variability increases the likelihood that results can be interpreted and replicated.

Reduction of Confounding Variables

Extraneous, or confounding, variables affect the detection of behavioral change due to the IV. Only by eliminating or minimizing external sources of variability can data be judged as accurately reflecting performance. Subjects should be selected that are similar along extra-experimental dimensions in order to reduce extraneous sources of variability. For example, it is common practice to use

animals from the same litter or to select human participants on the basis of age, level of education, or socioeconomic status. Environmental history of an organism can also influence the target behavior; therefore, subject selection methods should attempt to minimize differences between subjects. Some types of confounding variables cannot be removed, and the researcher must design an experiment to minimize their effects.

Steady State Behavior

Single-subject designs rely on the collection of steady state baseline data prior to the administration of the IV. Steady states are obtained by exposing the subject to only one condition consistently until behavior stabilizes over time. Stabilization is determined by graphically examining the variability in behavior. Stability can be defined as a pattern of responding that exhibits relatively little variation in its measured dimensional quantities over time.

Stability criteria specify the standards for evaluating steady states. Dimensions of behavior such as duration, latency, rate, and intensity can be judged as stable or variable during the course of experimental study, with rate most commonly used to determine behavioral stability. Stability criteria must set limits on two types of variability over time. The first is systematic increases and decreases of behavior, or *trend*, and the second is unsystematic changes in behavior, or *bounce*. Only when behavior is stable, without trend or bounce, should the next condition be introduced. Specific stability criteria include time, visual inspection of graphical data, and simple statistics. Time criteria can designate the number of experimental sessions or discrete period in which behavior stabilizes. The time criterion chosen must encompass even the slowest subject. A time criterion allowing for longer exposure to the condition may needlessly lengthen the experiment if stability occurs rapidly; on the other hand, behavior might still be unstable, necessitating experience and good judgment when a time criterion is used. A comparison of steady state behavior under baseline and different experimental conditions allows researchers to examine the effects of the IV.

Scientific Discovery Through Data Analysis

Single-subject designs use visual comparison of steady state responding between conditions as the primary method of data analysis. Visual analysis usually involves the assessment of several variables evident in graphed data. These variables include upward or

downward trend, the amount of variability within and across conditions, and differences in means and stability both within and across conditions. Continuous data are displayed against the smallest unit of time that is likely to show systematic variability. Cumulative graphs provide the greatest level of detail by showing the distribution of individual responses over time and across various stimulus conditions. Data can be summarized with less precision by the use of descriptive statistics such as measures of central tendency (mean and median), variation (interquartile range and standard deviation), and association (correlation and linear regression). These methods obscure individual response variability but can highlight the effects of the experimental conditions on responding, thus promoting steady states. Responding summarized across individual sessions represents some combination of individual responses across a group of sessions, such as mean response rate during baseline conditions. This method should not be the only means of analysis but is useful when one is looking for differences among sets of sessions sharing common characteristics.

Single-subject design uses ongoing behavioral data to establish steady states and make decisions about the experimental conditions. Graphical analysis is completed throughout the experiment, so any problems with the design or measurement can be uncovered immediately and corrected. However, graphical analysis is not without criticism. Some have found that visual inspection can be insensitive to small but potentially important differences of graphic data. When evaluating the significance of data from this perspective, one must take into account the magnitude of the effect, variability in data, adequacy of experimental design, value of misses and false alarms, social significance, durability of behavior change, and number and kinds of subjects. The best approach to analysis of behavioral data probably uses some combination of both graphical and statistical methods because each approach has relative advantages and disadvantages.

Judging Significance

Changes in level, trend, variability, and serial dependency must be detected in order for one to evaluate behavioral data. *Level* refers to the general magnitude of behavior for some specific dimension. For example, 40 responses per minute is a lower level than 100 responses per minute. *Trend* refers to the increasing or decreasing nature of behavior change. *Variability* refers to changes in behavior from measurement to measurement. *Serial dependency* occurs when a measurement obtained during one time period is related to a value obtained earlier.

Several features of graphs are important, such as trend lines, axis units, number of data points, and condition demarcation. Trend lines are lines that fit the data best within a condition. These lines allow for discrimination of level and may assist in discrimination of behavioral trends. The axis serves as an anchor for data, and data points near the bottom of a graph are easier to interpret than data in the middle of a graph. The number of data points also seems to affect decisions, with fewer points per phase improving accuracy.

Generality

Generality, or how the results of an individual experiment apply in a broader context outside the laboratory, is essential to advancing science. The dimensions of generality include subjects, response classes, settings, species, variables, methods, and processes. Single-subject designs typically involve a small number of subjects that are evaluated numerous times, permitting in-depth analysis of these individuals and the phenomenon in question, while providing *systematic replication*. Systematic replication enhances generality of findings to other populations or conditions and increases internal validity. The *internal validity* of an experiment is demonstrated when additional subjects demonstrate similar behavior under similar conditions; although the absolute level of behavior may vary among subjects, the relationship between the IV and the relative effect on behavior has been reliably demonstrated, illustrating generalization.

BEHRENS-FISHER t' STATISTIC

The Behrens-Fisher t' statistic can be employed when one seeks to make inferences about the means of two normal populations without assuming the variances are equal. The statistic was offered first by W. U. Behrens in 1929 and reformulated by Ronald A. Fisher in 1939:

$$t' = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{s_1^2/n_1 + s_2^2/n_2}} = t_1 \sin \theta - t_2 \cos \theta,$$

where sample mean $\bar{x}_1$ and sample variance s_1^2 are obtained from the random sample of size n_1 from the normal distribution with mean μ_1 and variance σ_1^2 , $t_1 = (\bar{x}_1 - \mu_1) / \sqrt{s_1^2/n_1}$ has a t distribution with $v_1 = n_1 - 1$ degrees of freedom, the respective quantities with subscript 2 are defined similarly, and $\tan \theta = (s_1 / \sqrt{n_1}) / (s_2 / \sqrt{n_2})$ or $\theta = \tan^{-1}[(s_1 / \sqrt{n_1}) / (s_2 / \sqrt{n_2})]$. The distribution of t' is the Behrens-Fisher distribution. It is, hence, a mixture of the two t distributions. The problem arising when one tries to test the normal population means without making any assumptions about their variances is referred to as the Behrens-Fisher problem or as the two means problem.

Under the usual null hypothesis of $H_0: \mu_1 = \mu_2$, the test statistic t' can be obtained and compared with the percentage points of the Behrens-Fisher distribution. Tables for the Behrens-Fisher distribution are available, and the table entries are prepared on the basis of the four numbers $v_1 = n_1 - 1$, $v_2 = n_2 - 1$, θ , and the Type I error rate α . For example, Ronald A. Fisher and Frank Yates in 1957 presented significance points of the Behrens-Fisher distribution in two tables, one for v_1 and $v_2 = 6, 8, 12, 24, \infty$; $\theta = 0^\circ, 15^\circ, 30^\circ, 45^\circ, 60^\circ, 75^\circ, 90^\circ$; and $\alpha = .05, .01$, and the other for v_1 that is greater than $v_2 = 1, 2, 3, 4, 5, 6, 7$; $\theta = 0^\circ, 15^\circ, 30^\circ, 45^\circ, 60^\circ, 75^\circ, 90^\circ$ and $\alpha = .10, .05, .02, .01$. Seock-Ho Kim and Allan S. Cohen in 1998 presented significance points of the Behrens-Fisher distribution for v_1 that is greater than

$v_2 = 2, 4, 6, 8, 10, 12$; $\theta = 0^\circ, 15^\circ, 30^\circ, 45^\circ, 60^\circ, 75^\circ, 90^\circ$; and $\alpha = .10, .05, .02, .01$, and also offered computer programs for obtaining tail areas and percentage values of the Behrens-Fisher distribution.

Using the Behrens-Fisher distribution, one can construct the $100(1 - \alpha)\%$ interval that contains $\mu_1 - \mu_2$ with

$$\bar{x}_1 - \bar{x}_2 \pm t'_{\alpha/2}(v_1, v_2, \theta) \sqrt{s_1^2/n_1 + s_2^2/n_2},$$

where the probability that $t' > t'_{\alpha/2}(v_1, v_2, \theta)$ is $\alpha/2$ or, equivalently, $\Pr[t' > t'_{\alpha/2}(v_1, v_2, \theta)] = \alpha/2$.

This entry first illustrates the statistic with an example. Then related methods are presented, and the methods are compared.

Example

Driving times from a person's house to work were measured for two different routes with $n_1 = 5$ and $n_2 = 11$. The ordered data from the first route are 6.5, 6.8, 7.1, 7.3, 10.2, yielding $\bar{x}_1 = 7.580$ and $s_1^2 = 2.237$, and the data from the second route are 5.8, 5.8, 5.9, 6.0, 6.0, 6.0, 6.3, 6.3, 6.4, 6.5, 6.5, yielding $\bar{x}_2 = 6.136$ and $s_2^2 = 0.073$. It is assumed that the two independent samples were drawn from two normal distributions having means μ_1 and μ_2 and variances σ_1^2 and σ_2^2 , respectively. A researcher wants to know whether the average driving times differed for the two routes.

The test statistic under the null hypothesis of equal population means is $t' = 2.143$ with $v_1 = 4$, $v_2 = 10$, and $\theta = 83.078$. From the computer program, $\Pr(t' > 2.143) = .049$, indicating the null hypothesis cannot be rejected at $\alpha = .05$ when the alternative hypothesis is nondirectional, $H_a: \mu_1 \neq \mu_2$, because $p = .098$. The corresponding 95% interval for the population mean difference is $[-0.421, 3.308]$.

Related Methods

The Student's t test for independent means can be used when the two population variances are assumed to be equal and $\sigma_1^2 = \sigma_2^2 = \sigma^2$:

$$t = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{s_p^2/n_1 + s_p^2/n_2}},$$

where the pooled variance that provides the estimate of the common population variance σ^2 is defined as $s_p^2 = [(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2] / (n_1 + n_2 - 2)$. It has a t distribution with $v = n_1 + n_2 - 2$ degrees of freedom. The example data yield the Student's $t = 3.220$, $v = 14$, the two-tailed $p = .006$, and the 95% confidence interval of $[0.482, 2.405]$. The null hypothesis of equal

population means is rejected at the nominal $\alpha = .05$, and the confidence interval does not contain 0.

When the two variances cannot be assumed to be the same, one of the solutions is to use the Behrens–Fisher t' statistic. There are several alternative solutions. One simple way to solve the two means problem, called the smaller degrees of freedom t test, is to use the same t' statistic that has a t distribution with different degrees of freedom

$$t' \sim t[\min(\nu_1, \nu_2)],$$

where the degrees of freedom is the smaller value of ν_1 or ν_2 . Note that this method should be used only if no statistical software is available because it yields a conservative test result and a wider confidence interval. The example data yield $t' = 2.143$, $\nu = 4$, the two-tailed $p = .099$, and the 95% confidence interval of $[-0.427, 3.314]$. The null hypothesis of equal population means is not rejected at $\alpha = .05$, and the confidence interval contains 0.

B. L. Welch in 1938 presented an approximate t test. It uses the same t' statistic that has a t distribution with the approximate degrees of freedom ν' :

$$t' \sim t(\nu'),$$

Where $\nu' = 1 / [c^2 / \nu_1 + (1 - c)^2 / \nu_2]$ with $c = (s_1^2 / n_1) / [(s_1^2 / n_1) + (s_2^2 / n_2)]$. The approximation is accurate when both sample sizes are 5 or larger. Although there are other solutions, Welch's approximate t test might be the best practical solution to the Behrens–Fisher problem because of its availability from the popular statistical software, including SPSS (an IBM company, formerly called PASW® Statistics) and SAS. The example data yield $t' = 2.143$, $\nu' = 4.118$, the two-tailed $p = .097$, and the 95% confidence interval of $[-0.406, 3.293]$. The null hypothesis of equal population means is not rejected at $\alpha = .05$, and the confidence interval contains 0.

In addition to the previous method, the Welch–Aspin t test employs an approximation of the distribution of t' by the method of moments. The example data yield $t' = 2.143$, and the critical value under the Welch–Aspin t test for the two-tailed test is 2.715 at $\alpha = .05$. The corresponding 95% confidence interval is $[-0.386, 3.273]$. Again, the null hypothesis of equal population means is not rejected at $\alpha = .05$, and the confidence interval contains 0.

Comparison of Methods

The Behrens–Fisher t' statistic and the Behrens–Fisher distribution are based on Fisher's fiducial approach. The

approach is to find a fiducial probability distribution that is a probability distribution of a parameter from observed data. Consequently, the interval that involves $t'_{\alpha/2}(\nu_1, \nu_2, \theta)$ is referred to as the $100(1 - \alpha)\%$ fiducial interval.

The Bayesian solution to the Behrens–Fisher problem was offered by Harold Jeffreys in 1940. When uninformative uniform priors are used for the population parameters, the Bayesian solution to the Behrens–Fisher problem is identical to that of Fisher's in 1939. The Bayesian highest posterior density interval that contains the population mean difference with the probability of $1 - \alpha$ is identical to the $100(1 - \alpha)\%$ fiducial interval.

There are many solutions to the Behrens–Fisher problem based on the frequentist approach of Jerzy Neyman and Egon S. Pearson's sampling theory. Among the methods, Welch's approximate t test and the Welch–Aspin t test are the most important ones from the frequentist perspective. The critical values and the confidence intervals from various methods under the frequentist approach are in general different from those of either the fiducial or the Bayesian approach. For the one-sided alternative hypothesis, however, it is interesting to note that the generalized extreme region to obtain the generalized P developed by Kam-Wah Tsui and Samaradasa Weerahandi in 1989 is identical to the extreme area from the Behrens–Fisher t' statistic.

The critical values for the two-sided alternative hypothesis at $\alpha = .05$ for the example data are 2.776 for the smaller degrees of freedom t test, 2.767 for the Behrens–Fisher t' test, 2.745 for Welch's approximate t test, 2.715 for the Welch–Aspin t test, and 2.145 for the Student's t test. The respective 95% fiducial and confidence intervals are $[-0.427, 3.314]$ for the smaller degrees of freedom test, $[-0.421, 3.308]$ for the Behrens–Fisher t' test, $[-0.406, 3.293]$ for Welch's approximate t test, $[-0.386, 3.273]$ for the Welch–Aspin t test, and $[0.482, 2.405]$ for the Student's t test. The smaller degrees of freedom t test yielded the most conservative result with the largest critical value and the widest confidence interval. The Student's t test yielded the smallest critical value and the shortest confidence interval. All other intervals lie between these two intervals. The differences between many solutions to the Behrens–Fisher problem might be less than their differences from the Student's t test when sample sizes are greater than 10.

The popular statistical software programs SPSS and SAS produce results from Welch's approximate t test and the Student's t test, as well as the respective confidence intervals. It is essential to have a table that contains the percentage points of the Behrens–Fisher distribution or computer programs that can calculate the tail areas and percentage values in order to use the

Behrens-Fisher t' test or to obtain the fiducial interval. Note that Welch's approximate t test may not be as effective as the Welch-Aspin t test. Note also that the sequential testing of the population means on the basis of the result from either *Levene's test* of the equal population variances from SPSS or the folded F test from SAS is not recommended in general because of the complicated nature of control of the Type I error (rejecting a true null hypothesis) in the sequential testing.

BELMONT REPORT

The Belmont Report is an authoritative document governing the ethical conduct of research involving human subjects. While it was originally conceived for biomedical and behavioral research, its principles have been employed and expanded on in other disciplinary

fields such as philosophy, law, political science, sociology, and computer science. This entry presents an overview of the Belmont Report's history, its three principles and their applications, and the issues that have been raised since its inception.

History

The Belmont Report was preceded by a number of other ethical codes developed since 1945 in order to protect human subjects against abuse. The Nuremberg Code, published in 1947 after the Nuremberg War Crime Trials revealed Nazi doctors' exploitative experiments with concentration camp prisoners, offers a set of guidelines to safeguard human subjects' physical and mental safety during clinical trials. The guidelines laid out by the Nuremberg Code were further expanded by the World Medical Association with the 1964 Declaration of Helsinki, focusing on physicians' ethical conduct when combining research and clinical practice.

A series of disreputable biomedical studies were also being conducted in the United States during the same period, yet not until 1978 did the public outcry become so overwhelming as to warrant congressional action. In the 1950s, a controversial hepatitis study was conducted among children with developmental disabilities attending the Willowbrook State School, deliberately infecting them with active hepatitis to examine the transmission of the disease. That same decade, pregnant women unknowingly participated in an experimental study of a new drug—thalidomide—to treat nausea, which was subsequently proven to cause birth defects. Other dubious biomedical studies followed suit, including an investigation into the spread of cancer by injecting live cancer cells into ailing elderly patients at the Jewish Chronic Disease Hospital in the 1960s and the study of contraceptive pills' efficacy involving unaware and poverty-stricken women in San Antonio, TX, in the 1970s.

The most infamous of the series of unethical medical studies in the United States was the Tuskegee syphilis study, whereby African American male farmers with syphilis were observed, tested, and left untreated between 1932 and 1972 to understand the natural progression of a disease that was known to affect a wider population. The human subjects were promised free medical care while being subjected to placebo treatments without their knowledge. Upon the revelation of the study's methods, the U.S. Congress enacted the National Research Act (Pub. L. 93–348) in 1974, standardizing institutional review boards' ethical oversight of studies with a research component involving human subjects. Additionally, it authorized the appointment of

the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research involving 11 members representing civil society and professionals from the fields of medicine, law, psychology, and ethics.

Following monthly public consultations over a period of 4 years, including intensive deliberations at the Belmont Conference Center in February 1976, the commission formally issued *The Belmont Report: Ethical Principles and Guidelines for the Protection of Human Subjects of Research* on September 30, 1978. It formally appeared in the Federal Register on April 18, 1979. The document begins by making the distinction between medical practice and research. Whereas the former alludes to the application of widely accepted interventions with reasonable expectations of enhancing health and well-being, the latter is mainly geared toward hypothesis testing and the production of generalizable knowledge. In situations where clinical practice involves an element that can be considered as research, such as when new techniques need to be assessed for safety and efficacy, the Belmont Report requires ethical review and approval. The remaining sections of the report discuss the principles for ethical research involving human subjects and their applications.

Core Principles

The 5,500-word Belmont Report identifies three core principles for the conduct of ethically sound research involving human participants: respect for persons, beneficence, and justice.

Respect for Persons

Respect for persons in the Belmont Report is essentially framed as acknowledging the autonomy of human subjects. Under this principle, human subjects should be treated as autonomous agents capable of making self-directed choices when it comes to their participation in research. Consequently, when their capacity for self-determination is diminished due to immaturity, illness, mental or physical disability, or social disadvantage, additional measures should be taken for their protection.

The direct application of this principle involves securing informed consent. All relevant information regarding the study's purposes, procedures, and associated benefits and risks must be disclosed to human subjects. Respect entails that subjects be allowed to freely ask questions and withdraw from the study without reprisal, and their full understanding of the conditions surrounding their participation must be guaranteed by presenting information in a manner that is clear, organized, and

undemanding. Consent must also be given voluntarily and not out of compliance, fear, or manipulation by offering inappropriate or disproportionate rewards. While autonomous decision-making must be assumed and granted to the fullest extent possible, this principle indicates that special measures may be warranted when subjects' capacities for comprehension are restricted or impaired by immaturity, mental or physical afflictions, or language limitations. Such a situation justifies the involvement of authorized third parties to exercise discretion and act in the human subject's best interest.

Beneficence

The Belmont Report's principle of beneficence involves two main dimensions: not doing harm and maximizing possible benefits while minimizing possible harms. This principle invokes the conduct of a risk-benefit analysis. This will allow researchers to make judgments on whether it is appropriate to renounce a potentially beneficial course of action when the harm it may generate outweighs its conceivable benefits. The nature and magnitude of risks and benefits will naturally differ when evaluated at the individual and social level in either the short term or the long term. For instance, study findings may benefit the wider society in the long term in the absence of direct advantages to the research subjects. In such situations, the Belmont Report suggests a systematic and rigorous examination of the nature, probability, and severity of harms and benefits arising from the study. To make such judgments as precise and accurate as possible, the analysis must include clear and explicit descriptions of the study's implications on the subject's psychological, physical, legal, social, and economic well-being. Additionally, there must be a conscious and thorough effort to consider possible alternatives offering comparable benefits while generating the least likelihood and magnitude of risks.

Justice

The Belmont Report conceptualizes justice as the fair distribution of the risks of research across society. It dictates that the benefits generated by publicly funded research must be shared equally among society regardless of wealth or financial status and that the involvement of subjects who are unable to benefit from the outcomes of research be avoided as much as possible.

As a matter of application, this principle manifests as fairness in the procedures and outcomes of selecting research subjects. Justice operates at two levels: individual and social. Individual justice requires researchers to act objectively when choosing subjects for high-risk research, avoiding social, racial, sexual, and cultural

biases. Consequently, this also implies the need for researchers to ensure that the recipients of beneficial studies are not limited to groups that are already privileged. Social justice, on the other hand, avoids the systematic recruitment of vulnerable populations in risk-laden research. The involvement of specific groups such as racial minorities or the underprivileged must be based on the relevance of their demographic characteristics to the problem or condition being studied—not due to their accessibility or likelihood of being coerced to participate. As such, the Belmont Report recommends an order of preference when recruiting subjects for research purposes (such as considering adults before children) and keeping the involvement of vulnerable populations to a minimum, only involving them when the nature of the condition or treatment being examined so requires.

Issues and Contemporary Reinterpretations

The Belmont Report is a critical document that has revolutionized the conduct of research both within and beyond the medical sciences. Its enduring quality can be attributed to its clarity and succinctness, although several issues have been raised since its inception regarding its capacity to comprehensively address the dilemmas arising from human research. Some authors argue that the principles of respect for persons, beneficence, and justice can be applied more broadly than what was stipulated in the Belmont Report. For instance, respect for persons does not only involve securing informed consent prior to research implementation but also ensuring that the participants are treated with dignity and fairness in all phases of the study and throughout the duration of their participation.

The biomedical and behavioral focus of the Belmont Report also limits its scope outside these disciplines. This was acknowledged by the Belmont Report's authors themselves in a footnote within the document and is a limitation that proves particularly salient in community-based research. Participatory methodologies, which are now widely employed in the health and social sciences, employ the term *participants* as opposed to the Belmont Report's *human subjects* to more appropriately capture the nature of the research relationship.

One of Belmont Report's more prominent criticisms is the protective stance it espouses and its negative implications. Categorical declarations of vulnerability are argued to generate unintended harms by promoting paternalism, perpetuating stereotypes, and conflating vulnerability with a lack of autonomy.

They are also viewed to lead to undue and unnecessary exclusion of those who would otherwise be interested in participating in research. Current debates on ethical research have evolved from protecting disenfranchised individuals from exploitative biomedical experiments into avoiding subtle or hidden forms of oppression and systemic exclusion as well as enhancing the inclusion and participation of disadvantaged or marginalized populations. Discounting the participation of vulnerable groups, even when well-intended, can also lead to harmful deprivation of data and findings that could otherwise improve existing interventions and services.

While the Belmont Report reflects a necessary response to the social, cultural, and political climate of its time, recent developments have cast doubt on some of its premises in light of contemporary challenges. The processes of globalization and digitalization have brought forth a new set of ethical dilemmas and theoretical tools that challenge the concepts it laid out. The spread of feminist and non-Western bioethical perspectives have broadened the notions of harm and justice, revealing power hierarchies and various forms of bias (gender, ethnic, and cultural, among others) not addressed in the Belmont Report. These alternative paradigms have introduced additional dimensions to existing formulations of ethical and responsible research, including cultural sensitivity, respect for diversity, and epistemic justice. Contemporary ethicists also juxtapose the Belmont Report's individualism against a collectivist position that considers research's risks and benefits to relationships and communal life.

The practice of clinical medicine is also changing in ways that challenge the report's distinction between medical practice as standard treatment with a reasonable expectation of improving health on the one hand and medical research as the systematic process of generating generalizable knowledge on the other. Increasingly, learning, data collection, and research are seen as essential processes of quality service delivery. Given that the Belmont Report stipulates ethical review and oversight for all research-related activity, the question arises whether this should be applied in an all-encompassing way or whether exceptions should be made for learning activities presenting minimal risks. Additionally, some authors have pointed out how nonmaleficence is invoked implicitly in the Belmont Report, arguing for a deliberate inclusion of this principle.

More recently, the emergence of internet and data technologies as a research tool and space has generated possibilities and concerns not anticipated by the Belmont Report. Digital platforms now allow consent to be sought and secured by ticking a box in an online form and

adding a digital signature. While convenient, this raises concerns regarding the extent and depth of the respondent's understanding of the conditions surrounding his or her participation. Digital settings are also particularly susceptible to data breach and misuse, giving rise to harmful outcomes such as reputational damage and privacy infringement that can further result in psychological or social distress. The intense connectivity enabled by online platforms and internet technologies has amassed huge swaths of data that can feed beneficial research, yet it has also led to concerns about surveillance and a lack of transparency as to how these data are accessed and used. For this, additional measures have been recommended especially with regard to anonymization and the protection of participants' personal information during data collection, archiving, and dissemination. Further operationalizing the Belmont Report in the context of digital research, *The Menlo Report: Ethical Principles Guiding Information and Communication Technology Research* was published in 2012, adding respect for law and public interest as a fourth principle to specifically tackle issues of transparency and accountability.

Notwithstanding these limitations, the suite of ethical guidelines and frameworks that branched out from the Belmont Report is a testament to its legacy in ethical decision-making. It remains to be seen how these principles will continue to be applied and developed in the name of ethical and responsible research.

BENEFICENCE

This entry presents the principle of beneficence in research involving humans. The concept is most concrete as used in medical research, which is the focus of this entry, but the concept is also central to social science research ethics. Beneficence is usefully detailed in the ethical theory of American ethicists Tom L. Beauchamp and James F. Childress. Their theory has been dominant worldwide for 40 years and has continued to develop in the eight editions of their book *Principles of Biomedical Ethics*.

Protection of Human Subjects in Biomedical Research—the Belmont Report

Experimental research on human beings attracted notoriety during the 1946–1947 Doctors' Trial in Nuremberg, Germany, on war crimes in concentration camps. The resulting Nuremberg Code (1947) influenced the Helsinki Declaration (1964), and together these documents offer a basis for the ethical obligations in biomedical research of free and informed consent, risk–benefit analysis, and review by independent committees (Briggle & Mitcham, 2018, pp. 134–138).

In the United States, however, it was the Tuskegee syphilis study in Alabama from 1932 to 1974 that did most to promote public awareness of ethical perspectives in biomedical experiments on human subjects. In that study, poor African American men suffering from syphilis received free medical examinations and food in exchange for participation but were not informed that they were enrolled in an experiment or even that they had syphilis, and they were deprived of effective treatment when penicillin became available in the 1940s (Briggle & Mitcham, 2018, pp. 140–143). Their low socioeconomic status made them vulnerable to manipulation and exploitation. Ethical obligations regarding free and informed consent, not causing harm, and promoting welfare were not met.

After public outrage over the Tuskegee syphilis study, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research published the Belmont Report (1979), providing a general framework of three basic ethical principles for biomedical research: respect for persons, beneficence, and justice (Beauchamp, 2010a, pp. 18–21). Beauchamp joined the employees of the commission in 1976 with the task to draft the report, expressing the views of the commissioners. The report presents a universal perspective on basic ethical principles (Beauchamp, 2010a, pp. 3, 6–9). Respect for persons relates to informed consent and means “that individuals should be treated as autonomous agents” and “that persons with diminished autonomy are entitled to protection” (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979. Part B, 1). Beneficence is an obligation to “do not harm” and “maximize possible benefits and minimize possible harms” (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979. Part B, 2, Part C, 2), which means it relates to risk–benefit assessment (Beauchamp, 2010a, pp. 21–22). Justice is an obligation of fairness in distribution of the benefits and burdens of research (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979. Part B, 3, Part C, 3), relates to the selection of research subjects, and “requires special levels of protection for vulnerable and disadvantaged parties” (Beauchamp, 2010a, p. 22).

The Belmont Report says that research involving human subjects is often justified by the principle of beneficence but states that considerations of informed consent, fairness in recruitment of research subjects, and risk assessment should set limits for social utility (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979. Part B, 2, Part C, 2), which means that the interests of research subjects outweigh those of the benefit to science and society. In his essay “Codes, Declarations, and Other Ethical Guidance for Human Subjects Research: The *Belmont Report*,” Beauchamp writes “it is doubtful that the question of how best to control utilitarian balancing was ever resolved by the National Commission” (2010a, pp. 25–26). Furthermore, he and Childress both argued that there were clear boundaries that the commission did not make between the principles of beneficence, nonmaleficence, and respect for autonomy. According to Beauchamp, many writers wrongly presume that the Belmont Report forms the foundation of his and Childress’s book *Principles of Biomedical Ethics*, first published in 1979. These two works were written at the same time and affected each other to the benefit of both (Beauchamp, 2010b, pp. 6–7). Beauchamp states that “*Principles of Biomedical Ethics*

became the sole work expressing my deepest philosophical convictions about principles” (Beauchamp, 2010b, p. 7).

The Four Principles of Biomedical Ethics

Unlike the Belmont Report, Beauchamp and Childress treat the principle of nonmaleficence as a separate principle not included in the principle of beneficence. They present a general moral framework of four principles for biomedical ethics: beneficence, nonmaleficence, justice, and respect for autonomy. As in the Belmont Report, these principles are not limited to the domain of biomedical ethics but are generally acknowledged as part of a common universal morality (Beauchamp & Childress, 2019, pp. 3–5). The four principles are equally important and presented as *prima facie* binding (Beauchamp & Childress, 2019, pp. ix, 15). As Beauchamp and Childress (2019, p. 15) write, “A *prima facie* obligation must be fulfilled unless it conflicts with an equal or stronger obligation.”

When competing moral considerations conflict in biomedical practice, the principles are specified, weighted, and balanced depending on the particular context in which they are applied (Beauchamp & Childress, 2019, pp. 15–24). Respect for autonomy is an obligation to respect and support autonomous decisions. Insufficiently autonomous persons are protected by the principles of nonmaleficence, beneficence, and justice. Nonmaleficence is an obligation to avoid causing physical and mental harm. Beneficence is an obligation to promote the good, hinder and remove harm and pain, and balance benefits against risks and costs. Justice is an obligation of fairness in the distribution of benefits, risks, and costs (Beauchamp & Childress, 2019, pp. 13, 156–159).

The Principle of Beneficence

The Belmont Report and Beauchamp and Childress’s theory both stress that the utilitarian social beneficence of biomedical experimentation should be limited by considerations of informed consent, fairness in recruitment of research subjects, and risk assessment. Beauchamp and Childress analyze two principles of beneficence: utility and positive beneficence (Beauchamp & Childress, 2019, p. 217).

Beauchamp and Childress’ principle of utility differs from the classical utilitarian principle of utility, which is an absolute principle. Instead, Beauchamp and Childress defend a principle of utility “as one among a number of equally important *prima facie* principles” (Beauchamp & Childress, 2019, p. 218). The principle of utility as a *prima facie* binding principle “can be applied to health policies through tools that analyze and assess benefits relative to costs and risks” (Beauchamp & Childress, 2019, p. 243). These tools are commonly referred to as

cost-effectiveness analysis and *cost-benefit analysis* (Beauchamp & Childress, 2019, p. 251).

Beauchamp and Childress state that morality requires that we take positive steps to contribute to people's welfare (positive beneficence) and not merely abstain from harming them (nonmaleficence; Beauchamp & Childress, 2019, p. 217). They write, "In our view, conflating nonmaleficence and beneficence into a single principle obscures critical moral distinctions as well as different types of moral theory" (Beauchamp & Childress, 2019, p. 156). Positive beneficence requires preventing or removing evil or harm by doing or promoting good, whereas nonmaleficence only requires avoiding intentionally inflicting evil or harm (Beauchamp & Childress, 2019, p. 157). The principle of beneficence therefore requires taking the positive step of performing risk-benefit analysis on biomedical experiments, with the risk-benefit relationship viewed "in terms of a ratio between the probability and magnitude of an anticipated benefit and the probability and magnitude of an anticipated harm" (Beauchamp & Childress, 2019, p. 244).

BERNOULLI DISTRIBUTION

The Bernoulli distribution is a discrete probability distribution for a random variable that takes only two possible values, 0 and 1. Examples of events that lead to

such a random variable include coin tossing (heads or tails), answers to a test item (correct or incorrect), outcomes of a medical treatment (recovered or not recovered), and so on. Although it is the simplest probability distribution, it provides a basis for other important probability distributions, such as the binomial distribution and the negative binomial distribution.

Definition and Properties

An experiment of chance whose result has only two possibilities is called a *Bernoulli trial* (or *Bernoulli experiment*). Let p denote the probability of success in a Bernoulli trial ($0 < p < 1$). Then, a random variable X that assigns value 1 for a success with probability p and value 0 for a failure with probability $1 - p$ is called a *Bernoulli random variable*, and it follows the Bernoulli distribution with probability p , which is denoted by $X \sim \text{Ber}(p)$. The probability mass function of $\text{Ber}(p)$ is given by

$$P(X = x) = p^x(1 - p)^{1-x}, \quad x = 0, 1.$$

The mean of X is p , and the variance is $p(1 - p)$. Figure 1 shows the probability mass function of $\text{Ber}(.7)$. The horizontal axis represents values of X , and the vertical axis represents the corresponding probabilities. Thus, the height is .7 at $X = 1$, and .3 for $X = 0$. The mean of $\text{Ber}(0.7)$ is 0.7, and the variance is .21.

Suppose that a Bernoulli trial with probability p is independently repeated for n times, and we obtain a random sample $X_1, X_2, \dots, X_n$. Then, the number of successes $Y = X_1 + X_2 + \dots + X_n$ follows the *binomial distribution* with probability p and the number of trials n , which is denoted by $Y \sim \text{Bin}(n, p)$. Stated in the opposite way, the Bernoulli distribution is a special case of the binomial distribution in which the number of trials n is 1. The probability mass function of $\text{Bin}(n, p)$ is given by

$$P(Y = y) = \frac{n!}{y!(n - y)!} p^y (1 - p)^{n - y},$$

$$y = 0, 1, \dots, n,$$

Figure 1 Probability Mass Function of the Bernoulli Distribution With $p = .7$

where $n!$ is the factorial of n , which equals the product $n(n-1)\cdots 2\cdot 1$. The mean of Y is np , and the variance is $np(1-p)$. Figure 2 shows the probability mass function of $\text{Bin}(10, .7)$, which is obtained as the distribution of the sum of 10 independent random variables, each of which follows $\text{Ber}(.7)$. The height of each bar represents the probability that Y takes the corresponding value; for example, the probability of $Y = 7$ is about .27. The mean is 7 and the variance is 2.1. In general, the distribution is skewed to the right when $p < .5$, skewed to the left when $p > .5$, and symmetric when $p = .5$.

Relationship to Other Probability Distributions

The Bernoulli distribution is a basis for many probability distributions, as well as for the binomial distribution. The number of failures before observing a success t times in independent Bernoulli trials follows the *negative binomial distribution* with probability p and the number of successes t . The *geometric distribution* is a special case of the negative binomial distribution in which the number of failures is counted before observing the first success (i.e., $t = 1$).

Assume a finite Bernoulli population in which individual members are denoted by either 0 or 1. If sampling is done by randomly selecting one member at each time *with replacement* (i.e., each selected member is returned to the population before the next selection is made), then the resulting sequence constitutes independent Bernoulli trials, and the number of successes follows the binomial distribution. If sampling is done at random but *without replacement*, then each of the individual selections is still a Bernoulli trial, but they are no longer independent of each other. In this case, the number of successes follows the *hypergeometric distribution*, which is specified by the population probability p , the number of trials n , and the population size m .

Various approximations are available for the binomial distribution. These approximations are extremely useful when n is large because in that case the factorials in the binomial probability mass function become prohibitively large and make probability calculations tedious. For example, by the central limit theorem, $Z = (Y - np) / \sqrt{np(1-p)}$ approximately follows the standard normal distribution $N(0, 1)$ when $Y \sim \text{Bin}(n, p)$. The constant 0.5 is often added to the denominator to improve the approximation (called *continuity correction*). As a rule of thumb, the normal approximation works well when either (a) $np(1-p) > 9$ or (b) $np > 9$ for $0 < p \leq .5$. The Poisson distribution with parameter np also well approximates $\text{Bin}(n, p)$ when n is large and p is small. The Poisson approximation works well if $n^{0.31}p > .47$; for example, $p > .19, .14$, and $.11$ when

Figure 2 Probability Mass Function of the Binomial Distribution With $p = 7$ and $n = 10$

$n = 20, 50$, and 100 , respectively. If $n^{0.31}p \geq .47$, then the normal distribution gives better approximations.

Estimation

Inferences regarding the population proportion p can be made from a random sample $X_1, X_2, \dots, X_n$ from $\text{Ber}(p)$, whose sum follows $\text{Bin}(n, p)$. The population proportion p can be estimated by the sample mean (or the sample proportion) $\hat{p} = \bar{X} = \sum_{i=1}^n X_i / n$, which is an unbiased estimator of p .

Interval estimation is usually made by the normal approximation. If n is large enough (e.g., $n > 100$), a $100(1 - \alpha)\%$ confidence interval is given by

$$\hat{p} \pm z_{\alpha/2} \sqrt{\frac{\hat{p}(1-\hat{p})}{n}},$$

where $\hat{p}$ is the sample proportion and $z_{\alpha/2}$ is the value of the standard normal variable that gives the probability $\alpha/2$ in the right tail. For smaller n s, the quadratic approximation gives better results:

$$\frac{1}{1 + z_{\alpha/2} / n} \left(\hat{p} + \frac{z_{\alpha/2}^2}{2n} \pm z_{\alpha/2} \sqrt{\frac{\hat{p}(1-\hat{p})}{n} + \frac{z_{\alpha/2}^2}{4n^2}} \right).$$

The quadratic approximation works well if $.1 < p < .9$ and n is as large as 25.

There are often cases in which one is interested in comparing two population proportions. Suppose that we obtained sample proportions $\hat{p}_1$ and $\hat{p}_2$ with sample sizes n_1 and n_2 , respectively. Then, the difference between the population proportions is estimated by the difference between the sample proportions $\hat{p}_1 - \hat{p}_2$. Its standard error is given by

$$SE(\hat{p}_1 - \hat{p}_2) = \sqrt{\frac{\hat{p}_1(1-\hat{p}_1)}{n_1} + \frac{\hat{p}_2(1-\hat{p}_2)}{n_2}}$$

from which one can construct a $100(1 - \alpha)$ confidence interval as

$$(\hat{p}_1 - \hat{p}_2) \pm Z_{\alpha/2} SE(\hat{p}_1 - \hat{p}_2).$$

Applications

Logistic Regression

Logistic regression is a regression model about the Bernoulli probability and used when the dependent variable takes only two possible values. Logistic regression models are formulated as *generalized linear models* in which the canonical link function is the logit link and the Bernoulli distribution is assumed for the dependent variable.

In the standard case in which there are K linear predictors $x_1, x_2, \dots, x_K$ and the dependent variable Y , which represents a Bernoulli random variable (i.e., $Y = 0, 1$), the logistic regression model is expressed by the equation

$$\ln \frac{p(x)}{1-p(x)} = b_0 + b_1 x_1 + \dots + b_K x_K,$$

where $\ln$ is the natural logarithm, $p(x)$ is the probability of $Y = 1$ (or the expected value of Y) given $x_1, x_2, \dots, x_K$, and $b_0, b_1, \dots, b_K$ are the regression coefficients. The left-hand side of the above equation is called the *logit*, or the *log-odds ratio*, of proportion p . The logit is symmetric about zero; it is positive (negative) if $p > .5$ ($p < .5$), and zero if $p = .5$. It approaches positive (negative) infinity as p approaches 1 (0). Another representation equivalent to the above is

$$p(x) = \frac{\exp(b_0 + b_1 x_1 + \dots + b_K x_K)}{1 + \exp(b_0 + b_1 x_1 + \dots + b_K x_K)}.$$

The right-hand side is called the *logistic* regression function. In either case, the model states that the distribution of Y given predictors $x_1, x_2, \dots, x_K$ is $\text{Ber}[p(x)]$, where the logit of $p(x)$ is determined by a linear combination of predictors $x_1, x_2, \dots, x_K$. The regression coefficients are estimated from N sets of observed data $(Y_i, x_{i1}, x_{i2}, \dots, x_{iK}), i = 1, 2, \dots, N$.

The Binomial Error Model

The binomial error model is one of the measurement models in the classical test theory. Suppose that there are n test items, each of which is scored either 1 (correct) or 0 (incorrect). The binomial error model assumes that the distribution of person i 's total score X_i given his or her "proportion-corrected" true score ζ_i ($0 < \zeta_i < 1$) is $\text{Bin}(n, \zeta_i)$:

$$P(X_i = x | \zeta_i) = \frac{n!}{x!(n-x)!} \zeta_i^x (1 - \zeta_i)^{n-x},$$

$$x = 0, 1, \dots, n.$$

This model builds on a simple assumption that for all items, the probability of a correct response for a person with true score ζ_i is equal to ζ_i , but the error variance, $n\zeta_i(1 - \zeta_i)$, varies as a function of ζ_i unlike the standard classical test model.

The observed total score $X_i = x_i$ serves as an estimate of $n\zeta_i$, and the associated error variance can also be estimated as $\hat{\sigma}_i^2 = x_i(n - x_i)/(n - 1)$. Averaging this error variance over N persons gives the overall error variance $\hat{\sigma}^2 = [\bar{x}(n - \bar{x}) - s^2]/(n - 1)$, where $\bar{x}$ is the sample mean of observed total scores over the N persons and s^2 is the sample variance. It turns out that by substituting $\hat{\sigma}^2$ and s^2 in the definition of reliability, the reliability of the n -item test equals the Kuder–Richardson formula 21 under the binomial error model.

History

The name *Bernoulli* was taken from Jakob Bernoulli, a Swiss mathematician in the 17th century. He made many contributions to mathematics, especially in calculus and probability theory. He is the first person who expressed the idea of the law of large numbers, along with its mathematical proof (thus, the law is also called *Bernoulli's theorem*). Bernoulli derived the binomial distribution in the case in which the probability p is a rational number, and his result was published in 1713. Later in the 18th century, Thomas Bayes generalized Bernoulli's binomial distribution by removing its rational restriction on p in his formulation of a statistical theory that is now known as Bayesian statistics.

BETA

Beta (β) refers to the probability of Type II error in a statistical hypothesis test. Frequently, the power of a test, equal to $1 - \beta$ rather than β itself, is referred to as a measure of quality for a hypothesis test. This entry discusses the role of β in hypothesis testing and its relationship with significance (α).

Hypothesis Testing and Beta

Hypothesis testing is a very important part of statistical inference: the formal process of deciding whether a particular contention (called the *null hypothesis*) is supported by the data, or whether a second contention (called the *alternative hypothesis*) is preferred. In this context, one can represent the situation in a simple 2×2 decision table in which the columns reflect the true (unobservable) situation and the rows reflect the inference made based on a set of data:

Decision	Null Hypothesis Is True/Preferred	Alternative Hypothesis Is True/Preferred
Fail to reject null hypothesis	Correct decision	Type II error
Reject null hypothesis in favor of alternative hypothesis	Type I error	Correct decision

The language used in the decision table is subtle but deliberate. Although people commonly speak of accepting hypotheses, under the maxim that scientific theories are not so much proven as *supported* by evidence, we might more properly speak of failing to reject a hypothesis rather than of accepting it. Note also that it may be the case that neither the null nor the alternative hypothesis is, in fact, true, but generally we might think of one as preferable over the other on the basis of evidence. Semantics notwithstanding, the decision table makes clear that there exist two distinct possible types of error: that in which the null hypothesis is rejected when it is, in fact, true; and that in which the null hypothesis is not rejected when it is, in fact, false. A simple example that helps one in thinking about the difference between these two types of error is a criminal trial in the U.S. judicial system. In that system, there is an initial presumption of innocence (null hypothesis), and evidence is presented in order to reach a decision to convict (reject the null

hypothesis) or acquit (fail to reject the null). In this context, a Type I error is committed if an innocent person is convicted, while a Type II error is committed if a guilty person is acquitted. Clearly, both types of error cannot occur in a single trial; after all, a person cannot be both innocent and guilty of a particular crime. However, *a priori* we can conceive of the probability of each type of error, with the probability of a Type I error called the significance level of a test and denoted by α , and the probability of a Type II error denoted by β , with $1 - \beta$, the probability of not committing a Type II error, called the *power of the test*.

Relationship With Significance

Just as it is impossible to realize both types of error in a single test, it is also not possible to minimize both α and β in a particular experiment with fixed sample size. In this sense, in a given experiment, there is a trade-off between α and β , meaning that both cannot be specified or guaranteed to be low. For example, a simple way to guarantee no chance of a Type I error would be to never reject the null hypothesis regardless of the data, but such a strategy would typically result in a very large β . Hence, it is common practice in statistical inference to fix the significance level at some nominal, low value (usually .05) and to compute and report β in communicating the result of the test. Note the implied asymmetry between the two types of error possible from a hypothesis test: α is held at some prespecified value, while β is not constrained. The preference for controlling α rather than β also has an analogue in the judicial example above, in which the concept of “beyond reasonable doubt” captures the idea of setting α at some low level, and where there is an oft-stated preference for setting a guilty person free over convicting an innocent person, thereby preferring to commit a Type II error over a Type I error. The common choice of .05 for α most likely stems from Sir Ronald Fisher’s 1926 statement that he “prefers to set a low standard of significance at the 5% point, and ignore entirely all results that fail to reach that level.” He went on to say that “a scientific fact should be regarded as experimentally established only if a properly designed experiment rarely fails to give this level of significance” (Fisher, 1926, p. 504).

Although it is not generally possible to control both α and β for a test with a fixed sample size, it is typically possible to decrease β while holding α constant if the sample size is increased. As a result, a simple way to conduct tests with high power (low β) is to select a sample size sufficiently large to guarantee a specified power for the test. Of course, such a sample size may be prohibitively large or even impossible, depending on the

nature and cost of the experiment. From a research design perspective, sample size is the most critical aspect of ensuring that a test has sufficient power, and *a priori* sample size calculations designed to produce a specified power level are common when designing an experiment or survey. For example, if one wished to test the null hypothesis that a mean μ was equal to μ_0 versus the alternative that μ was equal to $\mu_1 > \mu_0$, the sample size required to ensure a Type II error of β if $\alpha = .05$ is $n = \{\sigma(1.645 - \Phi^{-1}(\beta)) / (\mu_1 - \mu_0)\}^2$, where Φ is the standard normal cumulative distribution function and σ is the underlying standard deviation, an estimate of which (usually the sample standard deviation) is used to compute the required sample size.

The value of β for a test is also dependent on the effect size—that is, the measure of how different the null and alternative hypotheses are, or the size of the effect that the test is designed to detect. The larger the effect size, the lower β will typically be at fixed sample size, or, in other words, the more easily the effect will be detected.

BETA DISTRIBUTION

The beta distribution describes a probability distribution for a continuous random variable, say, X , that has the property $0 < X < 1$. Thus, this distribution can be used for modeling proportions, percentages, and other doubly bounded continuous random variables that can be linearly transformed to the $(0,1)$ interval.

Modeling doubly bounded variables requires a distribution that respects the variable's bounds and is able to deal with the fact that central tendency and dispersion in such variables are not independent of each other. Moreover, the distribution shapes should include extreme skew and even *bathtub* shapes. The beta distribution has only two parameters, but it is capable of modeling a considerable variety of distribution shapes. Its flexibility and straightforward interpretability have

made the beta distribution the most widely used distribution for modeling variables in $(0,1)$.

This entry begins with definitions of the beta distribution's density and cumulative density functions, and a brief overview of its genesis and its connections with other well-known *probability distributions*. Properties of the beta distribution are then described, with an emphasis on its strengths and limitations for modeling doubly bounded variables. Thereafter, methods of parameter estimation are discussed, including model diagnostics such as residuals and influence statistics. The entry concludes with a brief overview of multivariate distributions whose marginals are beta distributions.

Properties of the Beta Distribution

This section introduces the properties of the beta distribution, including an alternative parameterization that is used in beta regression models. It also describes relevant relationships between the beta distribution and other distributions.

Distribution Function

The probability density function (PDF) of the beta (α, β) distribution is

$$f(x, \alpha, \beta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1} (1-x)^{\beta-1}, \quad (1)$$

where $0 < x < 1$, $\alpha > 0$, $\beta > 0$, and Γ denotes the gamma function. Equation 1 implies that a beta distribution of $1 - X$ mirror images the distribution of X , that is, $f(1-x, \alpha, \beta) = f(x, \beta, \alpha)$.

The mean of a beta (α, β) distribution is

$$\mu = \alpha / (\alpha + \beta) \quad (2)$$

The variance of a beta distribution is

$$\sigma^2 = \left[\alpha\beta / (\alpha + \beta)^2 \right] / (\alpha + \beta + 1) = \mu(1-\mu) / (\alpha + \beta + 1), \quad (3)$$

which suggests a popular alternative parameterization of the beta distribution, namely a mean, μ , and a precision, $\phi = \alpha + \beta$. From Equation 3, we can see that ϕ is in the denominator of the variance and so larger ϕ implies lower σ^2 . This parameterization is the one most often used in generalized linear models (GLMs) for beta-distributed dependent variables.

The beta (α, β) distribution can assume a wide variety of shapes. When it has a mode or antimode, this occurs at $x = (\alpha - 1) / (\alpha + \beta - 2)$. When $\alpha < 1$ and $\beta < 1$, it has a U-shape with modes at 0 and 1 and an antimode. When $\alpha = 1$ and $\beta = 1$, it is flat (the uniform distribution).

When $(\alpha - 1)(\beta - 1) < 0$, the distribution is J- or reverse-J-shaped with no mode or antimode. When $\alpha > 1$ and $\beta > 1$, it has a unimodal shape; and if $\alpha = \beta$, it is symmetric.

The variance, σ^2 , of a $\text{beta}(\alpha, \beta)$ variable is less than $1/4$ for any α and β . To see this, recall that in Equation 3, the largest possible value of $\mu(1 - \mu)$ is $1/4$ (when $\mu = 1/2$), and the denominator in Equation 3 must be >1 . The variance has additional constraints. If $\alpha > 1$ and $\beta > 1$, then $\sigma^2 < 1/12$; and if $\alpha < 1$ and $\beta < 1$, then $1/12 < \sigma^2 < 1/4$.

Relations With Other Distributions

While there is no general agreement about the processes generating continuous random variables in $(0,1)$, the beta distribution has direct links to other kinds of random variables whose geneses have widely agreed-on accounts. Two of these that are relevant to the human sciences are as follows:

- (1) If Y_1 and Y_2 are gamma-distributed random variables with PDFs $g_1(\alpha, \delta)$ and $g_2(\beta, \delta)$, for $\delta > 0$, then $X = Y_1/(Y_1 + Y_2)$ has a $\text{beta}(\alpha, \beta)$ distribution.
- (2) If W_1 and W_2 are χ^2 -distributed random variables with PDFs $q_1(\gamma)$ and $q_2(\eta)$, for $\gamma > 0$ and $\eta > 0$, then $X = W_1/(W_1 + W_2)$ has a $\text{beta}(\gamma/2, \eta/2)$ distribution. If one or both of W_1 and W_2 are noncentral χ^2 variables, then X follows a noncentral beta distribution whose parameters include the noncentrality parameter(s).

Several other relationships between the beta and other distributions also are relevant for applications in the human sciences:

- (1) If X has a $\text{beta}(1, \beta)$ distribution, then it has a Kumaraswamy(1, β) distribution; and if X has a $\text{beta}(\alpha, 1)$ distribution, then it has a Kumaraswamy($\alpha, 1$) distribution. The Kumaraswamy distribution often is applied to modeling quantiles of X .
- (2) If X has a $\text{beta}(\alpha, \beta)$ distribution, then $\alpha X/(\beta(1 - X))$ has a $F(2\alpha, 2\beta)$ distribution.
- (3) If X has a $\text{beta}(\alpha, 1)$ distribution, then $-\ln(X)$ has an exponential(α) distribution. There also is an extensive literature on $X = \ln(Y)$ when X has a $\text{beta}(\alpha, \beta)$ distribution.

Parameter Estimation and Applications

This section begins by describing methods for estimating the parameters of the beta distribution and examples of its application. It then moves on to considerations

about estimation bias, model checking, and limitations of the beta distribution.

Parameter Estimation

The beta distribution's parameters may be estimated by method of moments or by maximum likelihood techniques. The latter is favored for GLMs with covariates predicting either or both of the parameters. Several authors such as Paolino (2001), Ferrari and Cribari-Neto (2004), and Smithson and Verkuilen (2006) present beta GLMs using the mean-precision parameterization described in Equations 2 and 3. Taking into account that the precision is negatively associated with dispersion, the beta GLM is a location–dispersion model in the sense of Smyth (1989). There are two submodels, typically using the following link functions:

$$\begin{aligned} \log(\mu_i/(1 - \mu_i)) &= \mathbf{x}_i^\top \boldsymbol{\beta} \\ \log(\phi_i) &= \mathbf{w}_i^\top \boldsymbol{\delta} \end{aligned} \quad (4)$$

where $\mathbf{x}$ and $\mathbf{w}$ are vectors of covariates and $\boldsymbol{\beta}$ and $\boldsymbol{\delta}$ are vectors of coefficients. The two sets of covariates may or may not overlap. Other link functions could be used (e.g., the cauchit or probit for the mean), but the logit and log link functions are the ones implemented in available software at the time this is written.

Applications

Early use of the beta distribution was primarily either as a means to form conjugate priors for binomial random variables or for theoretical purposes, such as its relationship with the F distribution. Only since 1993 has it been used for statistical modeling, as in GLMs.

Doubly bounded random variables occur throughout psychology and cognate areas such as political science, economics, and biology. The most commonplace examples in psychology include proportions and percentages, such as probability judgments, the proportion of the brain's volume occupied by a specific part of the brain, and the proportion of a period of time spent on an activity. Examples from economics include rates such as fractional repayments on debts, market shares, and capital structure. Many psychological scales are doubly bounded, and in some applications, it is sensible to treat the bounds as true scores (rather than as censored scores). Examples of this kind include analyses of Likert-type scale data and some kinds of summative scales (e.g., a quality of life index).

Model Checking and Extensions

Maximum likelihood estimation seems to work well for GLMs using the beta distribution, despite the fact that standard GLM regularity conditions do not apply to the beta distribution because it is not a member of the exponential family. There is some evidence that this may also hold for random-effects as well as fixed-effects models. Daniel Zimprich (2010) fitted a mixed-effects beta GLM, and Jay Verkuilen and Michael Smithson (2012) examined such models in some depth, along with Bayesian Markov chain Monte Carlo estimation approaches. Likewise, Yvonnick Noël and Bruno Dauvier (2007) developed item-response models for doubly bounded continuous scale items using the beta distribution, which Noël (2014) extended to unfolding models.

That said, there is some evidence of estimation bias, especially in the precision parameter submodel when sample sizes are small. Bias correction methods suggested by Ioannis Kosmidis and David Firth (2010) have been implemented in some software packages for beta GLMs such as the *betareg* package in R (Grün, Kosmidis, & Zeileis, 2012).

Model checking in beta GLMs has proved somewhat less straightforward, although *dfbetas* as influence statistics seem to work reasonably well and conventional residuals such as the Pearson also can be helpful. Espinheira, Ferrari, and Cribari-Neto (2008a, 2008b) discuss issues regarding the uses of influence statistics and residuals for model checking in beta GLMs. At the time of this writing, there is no agreed-on residual for beta GLMs, although several alternatives have been investigated.

Flexible though it is, the beta distribution is limited in its ability to capture some kinds of distribution shapes such as heavy-tailed or bimodal distributions. Some attempts have been made to extend beta GLMs for greater flexibility. Most of these have focused on mixture distribution models. Smithson and Segale (2009) and Smithson, Merkle, and Verkuilen (2011) employed mixture models for analyzing experimental data where they could assume that for at least one component distribution, the location parameter is known *a priori*. More generally, Hahn (2008) introduced the beta rectangular distribution, a mixture of a uniform and a beta distribution; and Migliorati, Di Brisco, and Ongaro (2018) presented a mixture of two beta distributions with arbitrary means but common variance. These mixture distributions yield identifiable GLMs with bounded likelihoods that have a greater variety of density shapes than the beta, especially in tail behavior and bimodality.

A major limitation of the beta distribution in applications to real data is the fact that its density is not defined at 0 or at 1. In applications where the data contain 0s and 1s, this limitation has been problematic.

One solution is a so-called *0-1-inflated model* (Ospina & Ferrari, 2012). Technically, this is a hurdle model, a mixture distribution with degenerate probability masses at 0 and 1 and the beta distribution for modeling data in the (0,1) interval.

Multivariate Extensions

There are two types of multidimensional extension of the beta distribution (i.e., multivariate distributions with beta marginals): compositional, where the variables must sum to 1 across dimensions, and noncompositional. The classic compositional distribution with beta marginals is the Dirichlet:

$$f(\mathbf{x}, \boldsymbol{\eta}) = \frac{1}{B(\boldsymbol{\eta})} \prod_{k=1}^K x_k^{\eta_k - 1}, \quad (5)$$

where

$$B(\boldsymbol{\eta}) = \frac{\prod_{k=1}^K \Gamma(\eta_k)}{\Gamma\left(\sum_{k=1}^K \eta_k\right)}, \eta_k > 0 \quad (6)$$

and $\sum_{k=1}^K x_k = 1$. The covariances in the Dirichlet PDF all are negative:

$$\sigma_{jk} = -\frac{\eta_j \eta_k}{\eta_0^2 (\eta_0 + 1)}. \quad (7)$$

The marginal PDFs for the Dirichlet distribution are $\text{beta}(\eta_k, \eta_0 - \eta_k)$, where $\eta_0 = \sum_{k=1}^K \eta_k$. Dirichlet regression models have been proposed and implemented in software.

Noncompositional multivariate extensions of the beta distribution have been provided in two forms. One is the standard multilevel (or mixed) model approach, as described by Verkuilen and Smithson (2012). The other is to use copulas to model the dependency structure separately from the marginal PDFs. Copulas are multivariate cumulative distribution functions with uniform marginal distributions, so a copula model often is estimated in two stages. The marginal PDFs are modeled and their parameter estimates are fed to their respective quantile functions, whose output then yields a multivariate distribution with uniform marginals. A copula model then is estimated using this multivariate distribution as input.

BETWEEN-SUBJECTS DESIGN

See Single-Case Research Design; Within-Subjects Design

BIAS

Bias is systematic error that occurs in the research enterprise. All research includes some forms of bias, and investigators are responsible for recognizing such potential when sharing their findings. Naming how different types of bias may or may not affect the quality of research conclusions is a central feature of the validation process. Consider, for example, what happens when comparing the behaviors of people who are classified into different groups and studied over time. If the groups are unequal at the beginning of a study, any subsequent variance between the groups cannot be explained using only the new research evidence. Uncontrolled and unnamed biases may be the cause of any differences between groups or changes that might occur over time. To minimize distortion in any research, it is incumbent on all investigators to define and explore the qualities and influence of bias.

When bias is not considered in the interpretation process, the credibility of conclusions is called into question. Thus, investigators within and across disciplines have collaborated to name the most common forms of biases they encounter. Studies of bias can be classified into one of three nested categories, each of which is explored by considering particular disciplinary assumptions and norms. Bias can be the result of distortions in theoretical logic, the design of a study, and/or the measurement and evaluation of variables.

Theoretical Bias

Bias in the theoretical logic of a research program or study involves flaws in critical thinking and the interpretation of evidence. This type of bias is commonly

detected by reviewing existing literature and looking for systematic flaws in the explicit and implicit assumptions generated as part of the research process. Advocates of a particular theory commonly evaluate the qualities of the arguments generated and the evidence used to support those arguments. Across theories, it is also possible to identify common argument forms and fallacies in how premises are generated and tested.

Generally speaking, arguments can take valid and invalid forms. Philosophers of science endeavor to distinguish between these types of arguments when naming bias. Pennock (2019), for example, described how the quest for truth simultaneously guides curiosity and generates moral norms that investigators are bound to imagine when conducting research. Vaughn (2019) named some of the common fallacies that are found in research and described valid and invalid argument forms.

Valid research, in Vaughn's model, systematically tests whether antecedent assumptions can be affirmed, whether consequences are explored well enough to disprove them should they be untrue, and whether hypothetical syllogisms comprised of two or more premises can be verified or refuted. Invalid research instigates bias when consequences are assumed to support an initial, unsubstantiated premise. Likewise, bias would be likely when consequences are assumed to be true even though initial antecedents are not supported. Starting a study with unequal groups, for example, could yield either of these two forms of argumentative bias if investigators did not find a way to control for such inequalities.

A second form of theoretical bias is apparent when the content of operating premises or assumptions is laden with fallacies. Fallacies in critical thinking are easy to overlook when investigators become too wedded to a particular set of beliefs or premises. Some fallacies are grounded in irrelevant premises (Vaughn, 2019). For example, appeals to ignorance about a topic or to tradition introduce bias in any truth claims because they are grounded in a lack of evidence. Likewise, raising irrelevant issues or distorting, weakening, or oversimplifying a theoretical premise serve as distractions because supporting evidence is unavailable.

Other fallacies are grounded in unacceptable premises. Creating a false dilemma or using the conclusion of an argument as a premise are two ways in which investigators can add theoretical inaccuracies into a quest for truth. Similarly, slippery slope claims about undesirable consequences or hasty generalizations using an inadequate sample to support claims about an entire group are common forms of theoretical bias. Taken as a whole, these forms of bias are sometimes called *experimenter expectancy effects* or *generalizability threats*. Biases related to the era in which some studies are conducted and/or to changes that may not be attributable

to the research are additional threats to theoretical validity, so much so that entire disciplines have been formulated to better understand the consequences of these biases.

Bias in Research Design

Research designs, the relations between variables under investigation, can be biased to such an extent that they cannot yield valid results even when theoretical claims are sound. Two classic explorations of how to address biases in experimental and quasi-experimental research design illustrate how investigators control distortion (Campbell & Stanley, 1963; Cook & Campbell, 1979). Since then, there has been a proliferation of studies on the biases associated with a broad range of research designs. Naming and controlling for internal and external biases that potentially distort research evidence strengthens the truth value of conclusions. Biases in research design, therefore, are commonly depicted as threats to internal and external validity.

Some of the most common sources of bias in research design proliferate from misunderstandings about the concept of randomization. Randomization, the reliance on chance-driven procedures when making decisions, is often used as a practical solution to bias that stems from uncontrollable error. In principle, when simple random sampling is repeated across multiple implementations of the same biased procedures, the repetition will result in a normal distribution of uncontrollable error. This procedure controls for bias when the same study is repeated often enough for normal distributions to emerge in the evidence. Yet, few studies are actually replicated often enough for simple random sampling to eliminate uncontrollable error from a research design.

Despite its usefulness in some situations, randomization often results in unequal groups when used in isolation, so much so that a number of design biases may be inferred. External to a study, for example, the participants selected for inclusion in one sample may not fully represent the distribution of members in the targeted population: Subsets of a population may be excluded or oversampled when participants are randomly selected. Names such as selection–treatment interaction as well as diffusion, compensatory equalization, or compensatory rivalry of treatments have been used to depict some of these external biases.

Internal to a study, a second source of bias is likely when the members of any sample are randomly assigned to one group or another: Subsets of the sample may be missing from one group and overrepresented in another. When left uncontrolled, these decisions results in exponential forms of error that can yield biased conclusions. Names such as selection–maturation interaction,

resentful demoralization, and experimental mortality have been used to depict some of these internal biases.

Investigators address both random selection and random assignment biases by identifying those forms of distortion that might undermine their theoretical claims and adding controls for such distortion into their research designs. Studies of bias in research design differ in the extent to which they focus on interventions or descriptive depictions of the concepts and constructs and the settings in which such observations occur (Larzelere, Kuhn, & Johnson, 2004; Rosenthal, 2002). Ideally, choices for addressing biases in research design become progressively more sophisticated as solutions to research problems become more truthful, and as truthful premises are accurately distinguished from false premises.

Measurement and Evaluation Bias

A third category of bias focuses on the use of data to answer research questions. First, the instrumentation used to track, measure, and interpret key concepts, constructs, or variables includes bias. Second, the methods used to aggregate data, compare variables, and answer research questions include sources of bias that warrant consideration.

The detection of measurement and evaluation biases hinge on how a research program balances questions of *objectivity*, *individuality*, and *solidarity* when making decisions. Criteria for objectivity lead investigators to rely on standardized tools that will yield predictable outcomes on repeated use, representing bias as any deviation from such standards. Criteria for individuality lead investigators to look for the relative uniqueness of each measurement encounter, expressing bias as distortion in the description of such uniqueness. Criteria for solidarity lead investigators to look for commonalities across measurement opportunities, depicting bias as inaccuracies in how such measurements are recorded and aggregated.

Investigators who endeavor to generate strong predictions or control outcomes place the strongest emphasis on objectivity when they construct measurement plans. They tend to rely on random sampling theory and address its concomitant forms of bias when determining what to measure and how to measure the ideas under investigation. *Psychometric measurement* approaches, for example, depend heavily on probability theory and randomization, drawing comparisons between hypothetical true scores and biased observed scores. In such work, bias is defined as a combination of known error and unknown error. Biases that are salient in individuals' reports of their own and others' experience is perhaps the most frequently studied form of psychometric bias.

Developmental measurement and its corresponding bias account for change as it emerges in the structure and

function of what is to be measured and/or in how people evolve over time. Individuality and solidarity are sometimes emphasized more than objectivity, but an ideal research plan balances all three concerns. Specialized applications of random sampling theory and its concomitant biases are used when the constructs can be defended and measured using standardized tools to track changes over time. Additional measurement approaches allow for the detection of structural changes in what is to be measured or to detect particular functions and change mechanisms, but each includes detectable biases. Detection of the physical and social-emotional changes that occur as adolescents progress through puberty, for example, requires respect for the highly individualized nature of hormonal change as well as aggregated evidence depicting age-related commonalities. Bias proliferates when measures designed for one purpose are used for another but is addressed when the limits of each tool are considered when interpreting results.

Interpretive measurement occurs when investigators celebrate individuality and narrow forms of solidarity by investigating bias (Thorkildsen, 2005). Interpretive research focuses on rule-governed descriptions of everyday events such as describing the world, challenging assumptions, discovering contrasting evidence, clarifying the dimensions of particular constructs, and resisting attempts to reify truth claims. Seeking dependable, credible evidence, investigators distinguish the respectable bias needed to place reasonable parameters on the scope of a research project and distorting bias that should be minimized. Recording observations with precision and relying on multiple methods of interpreting results help to restrict problematic bias.

The final source of bias emerges when investigators use statistical analyses and descriptive methods to report their findings. When tools of analysis do not align well with the instrumentation decisions, bias can yield invalid conclusions. When analytical tools align with the research questions and accommodate the types of biases embedded in the instrumentation process, truthful conclusions are likely.

Research as a Study of Bias

Depicting bias as systematic error places pressure on investigators to define truth as often as they offer claims about distortion. Disciplinary assumptions and the nature of the theories under consideration help investigators identify the parameters for determining bias by evaluating the qualities of arguments for their relative truth-value. Thoughtful exploration of design limitations and how well evidence yields informative truth places the study of bias at the heart of conducting strong research. Accepting that bias is a feature of all

research constrains curiosity and pressures investigators to consider the moral consequences of their claims.

BIASED ESTIMATOR

In many scientific research fields, statistical models are used to describe a system or a population, to interpret a phenomenon, or to investigate the relationship among various measurements. These statistical models often contain one or multiple components, called *parameters*, that are unknown and thus need to be estimated from the data (sometimes also called the *sample*). An estimator, which is essentially a function of the observable data, is biased if its expectation does not equal the parameter to be estimated.

To formalize this concept, suppose θ is the parameter of interest in a statistical model. Let $\hat{\theta}$ be its estimator based on an observed sample. Then $\hat{\theta}$ is a biased estimator if $E(\hat{\theta}) \neq \theta$, where E denotes the expectation operator. Similarly, one may say that $\hat{\theta}$ is an unbiased estimator if $E(\hat{\theta}) = \theta$. Some examples follow.

Example 1

Suppose an investigator wants to know the average amount of credit card debt of undergraduate students from a certain university. Then the population would be

all undergraduate students currently enrolled in this university, and the population mean of the amount of credit card debt of these undergraduate students, denoted by θ , is the parameter of interest. To estimate θ , a random sample is collected from the university, and the sample mean of the amount of credit card debt is calculated. Denote this sample mean by $\hat{\theta}_1$. Then $E(\hat{\theta}_1) = \theta$; that is, $\hat{\theta}_1$ is an unbiased estimator. If the largest amount of credit card debt from the sample, call it $\hat{\theta}_2$, is used to estimate θ , then obviously $\hat{\theta}_2$ is biased. In other words, $E(\hat{\theta}_2) \neq \theta$.

Example 2

In this example a more abstract scenario is examined. Consider a statistical model in which a random variable X follows a normal distribution with mean μ and variance σ^2 , and suppose a random sample $X_1, \dots, X_n$ is observed. Let the parameter θ be μ . It is seen in Example 1 that $\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i$, the sample mean of $X_1, \dots, X_n$, is an unbiased estimator for θ . But $\bar{X}^2$ is a biased estimator for μ^2 (or θ^2). This is because $\bar{X}$ follows a normal distribution with mean μ and variance $\frac{\sigma^2}{n}$. Therefore, $E(\bar{X}^2) = \mu^2 + \frac{\sigma^2}{n} \neq \mu^2$.

Example 2 indicates that one should be careful about determining whether an estimator is biased. Specifically, although $\hat{\theta}$ is an unbiased estimator for θ , $g(\hat{\theta})$ may be a biased estimator for $g(\theta)$ if g is a nonlinear function. In Example 2, $g(\theta) = \theta^2$ is such a function. However, when g is a linear function, that is, $g(\theta) = a\theta + b$ where a and b are two constants, then $g(\hat{\theta})$ is always an unbiased estimator for $g(\theta)$.

Example 3

Let $X_1, \dots, X_n$ be an observed sample from some distribution (not necessarily normal) with mean μ and variance σ^2 . The sample variance S^2 , which is defined as $\frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2$, is an unbiased estimator for σ^2 , while the intuitive guess $\frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})^2$ would yield a biased estimator. A heuristic argument is given here. If μ were known, $\frac{1}{n} \sum_{i=1}^n (X_i - \mu)^2$ could be calculated, which would be an unbiased estimator for σ^2 . But since μ is not known, it has to be replaced by $\bar{X}$. This replacement actually makes the numerator smaller. That is, $\sum_{i=1}^n (X_i - \bar{X})^2 \leq \sum_{i=1}^n (X_i - \mu)^2$ regardless of the value of μ . Therefore, the denominator has to be reduced a little bit (from n to $n-1$) accordingly.

A closely related concept is the bias of an estimator, which is defined as $E(\hat{\theta}) - \theta$. Therefore, an unbiased estimator can also be defined as an estimator whose bias is zero, while a biased estimator is one whose bias is nonzero. A biased estimator is said to underestimate the parameter if the bias is negative or overestimate the parameter if the bias is positive.

Biased estimators are usually not preferred in estimation problems, because in the long run, they do not provide an accurate “guess” of the parameter. Sometimes, however, cleverly constructed biased estimators are useful because although their expectation does not equal the parameter under estimation, they may have a small variance. To this end, a criterion that is quite commonly used in statistical science for judging the quality of an estimator needs to be introduced. The mean square error (MSE) of an estimator $\hat{\theta}$ for the parameter θ is defined as $E[(\hat{\theta} - \theta)^2]$. Apparently, one should seek estimators that make the MSE small, which means that $\hat{\theta}$ is “close” to θ . Notice that

$$\begin{aligned} E[(\hat{\theta} - \theta)^2] &= E[(\hat{\theta} - E\{\hat{\theta}\})^2] + (E\{\hat{\theta}\} - \theta)^2 \\ &= \text{Var}(\hat{\theta}) + \text{Bias}^2, \end{aligned}$$

meaning that the magnitude of the MSE, which is always nonnegative, is determined by two components: the variance and the bias of the estimator. Therefore, an unbiased estimator (for which the bias would be zero), if possessing a large variance, may be inferior to a biased estimator whose variance and bias are both small. One of the most prominent examples is the shrinkage estimator, in which a small amount of bias for the estimator gains a great reduction of variance. Example 4 is a more straightforward example of the usage of a biased estimator.

Example 4

Let X be a Poisson random variable, that is, $P(X = x) = \frac{e^{-\lambda} \lambda^x}{x!}$, for $x = 0, 1, 2, \dots$. Suppose the parameter $\theta = e^{-2\lambda}$, which is essentially $[P(X = 0)]^2$, is of interest and needs to be estimated. If an unbiased estimator, say $\hat{\theta}_1(X)$, for θ is desired, then by the definition of unbiasedness, it must satisfy $\sum_{x=0}^{\infty} \hat{\theta}_1(x) \frac{e^{-\lambda} \lambda^x}{x!} = e^{-2\lambda}$ or, equivalently, $\sum_{x=0}^{\infty} \frac{\hat{\theta}_1(x) \lambda^x}{x!} = e^{-\lambda}$ for all positive values of λ . Clearly, the only solution is that $\hat{\theta}_1(x) = (-1)^x$. But this unbiased estimator is rather absurd. For example, if $X = 10$, then the estimator $\hat{\theta}_1$ takes the value of 1, whereas if $X = 11$, then $\hat{\theta}_1$ is 1. As a matter of fact, a

much more reasonable estimator would be $\hat{\theta}_2(X) = e^{-2X}$, based on the maximum likelihood approach. This estimator is biased but always has a smaller MSE than $\hat{\theta}_1(X)$.

BINOMIAL DISTRIBUTION

The binomial distribution describes the results of repeated independent trials of an event for which the outcome space has two possible values (e.g., yes or no, true or false, heads or tails, success or failure), and each trial shares the same probability of success. The binomial distribution represents the probability of different combinations of successes or failures when the experiment is repeated n number of times, and X represents the number of successes in n trials. The probability that a single trial succeeds can be represented with parameter p . The probability that a single trial fails can be represented with parameter q . The sum of p and q must always equal 1. The mean of a binomial distribution is always $\mu = n \times p$, and the variance of X can be approximated by $\sigma^2 = n \times p \times q$. Some statistical inference can be made using the binomial distribution in specific examples. This entry presents a description of the history of the binomial distribution as well as the applications for statistical inference and some specific examples where the binomial distribution can be used.

History

The desire to calculate probabilities in games of chance led to the first studies of binomial distribution. Essentially, mathematically inclined gamblers wanted to calculate their probability of winning on a certain number of dice rolls. In 1713, Jakob Bernoulli, a Swiss

mathematician, published a proof that determined that the probability of X equaling a specified number, x , in n trials was equal to the x th term in the binomial expansion of the expression $(p + q)^n$, thus creating the binomial distribution.

The binomial distribution was used in 1936 to publish evidence of possible scientific chicanery by Gregor Mendel in the famous 1866 pea genetics experiments. Ronald Fisher noted that the reported laws of inheritance in peas would dictate that the number of certain colors of peas would have a binomial distribution, and the results reported by Mendel should have a probability of only about .1.

Applications for Statistical Inference

Any experiment using the binomial distribution has two assumptions: identical trials and independent trials. Identical trials is the assumption that p and q take on the same probability value across n number of trials. The compound binomial distribution does not assume identical trials. Independent trials is the assumption that subsequent trials are not affected by previous outcomes, so in order for the binomial distribution to be used, sampling with replacement must occur.

When the random variable X has parameters n and p in the binomial distribution, it is mathematically represented as $X \sim B(n, p)$. The probability that X is equal to a certain number, x , where $x = 0, 1, 2, \dots, n$, is given by the probability mass function:

$$f(x) = P(C = x) = C_x^n p^x q^{n-x},$$

where C_x^n is a mathematical combination, called the *binomial coefficient*, given by the equation:

$$C_x^n = \frac{n!}{x!(n-x)!}.$$

The cumulative distribution function for the binomial distribution is simply the sum of the probability mass function results for all applicable values. For example, the cumulative distribution function for the probability that X is less than or equal to a certain number, x , where $x = 0, 1, 2, \dots, n$, is given by

$$P(C \leq x) = \sum_{i=0}^x C_i^n p^i q^{n-i},$$

while the cumulative distribution function for the probability that X is greater than or equal to a certain number, x , where $x = 0, 1, 2, \dots, n$, is given by

$$P(C \geq x) = \sum_{i=x}^n C_i^n p^i q^{n-i}.$$

Properties

When p represents the probability of a success in one trial and n represents the number of trials, the expected value or mean of the binomial distribution is $\mu = n \times p$ and the variance is $\sigma^2 = n \times p \times q$, where q represents the probability of failure on one trial, or $1 - p$. If p is unknown, $\hat{p}$ can be estimated to represent p as an unbiased estimator such that $\hat{p} = \frac{x}{n}$, where x is the number of observed successes in n trials.

The mode of the binomial distribution is dependent on different cases of the distribution and can be calculated as

$$\text{Mode} = \begin{cases} \text{floor}[(n+1)p] & \text{if } (n+1)p \text{ is 0 or a noninteger,} \\ (n+1)p \text{ and } (n+1)p - 1 & \text{if } (n+1)p \in \{1, \dots, n\}, \\ n & \text{if } (n+1)p = n+1, \end{cases}$$

where $\text{floor}()$ is the floor function indicating the lowest previous integer in a series. For example, if a fair six-sided die is rolled six times, $n = 6$, $p = \frac{1}{6}$, so the mode would be $\text{floor}\left[(6+1)\frac{1}{6}\right]$, which is equal to $\text{floor}\left(\frac{7}{6}\right)$. When taking the lowest previous integer of $\frac{7}{6}$, the result is that the mode equals 1.

The median of the binomial distribution does not have a single formula; however, the median conforms to several statements, including

- (1) The median, m , must lie within the interval $\text{floor}(np) \leq m \leq \text{ceiling}(np)$ where $\text{floor}()$ is the lowest previous integer in a series and $\text{ceiling}()$ is the highest previous integer in a series.
- (2) The median must not be far from the mean such that
$$|mnp| \leq \min\{\ln 2, \max(p, 1-p)\}.$$
- (3) When $p = .5$ and n is odd, the median is a number in the interval:

$$\frac{1}{2}(n-1) \leq m \leq \frac{1}{2}(n+1).$$

- (4) When $p = .5$ and n is even, the median equals $\frac{n}{2}$.

Confidence Intervals

A number of methods exist for determining a confidence level for the probability of success in a binomial

distribution. The Wald method is the most commonly recommended method; other methods include the Clopper–Pearson interval, the Agresti–Coull method, and the Arcsine method.

The Clopper–Pearson method, sometimes known as the *exact method*, calculates a confidence interval based on the binomial distribution’s cumulative properties. When x is the number of successes observed in a binomial sample with n trials, the Clopper–Pearson method interval is given by

$$\frac{1}{1 + \frac{n-x+1}{x} F_{2(n-x+1), 2x, \frac{\alpha}{2}}} \leq p \leq \frac{\frac{x+1}{n-x} F_{2(x+1), 2(n-x), \frac{\alpha}{2}}}{1 + \frac{x+1}{n-x} F_{2(x+1), 2(n-x), \frac{\alpha}{2}}}.$$

For example, if in 10 trials there are three successes, the Clopper–Pearson method gives a 95% confidence interval of

$$\frac{1}{1 + \frac{10-3+1}{3} F_{16,6,0.025}} \leq p \leq \frac{\frac{3+1}{10-3} F_{8,14,0.025}}{1 + \frac{3+1}{10-3} F_{8,14,0.025}},$$

thus, $.087 \leq p \leq .607$.

Given that $\hat{p}$ is the proportion of successes representing the estimate of p , and z is the quantile from the standard normal distribution that corresponds to the desired error rate, α , the Wald method for calculating a

confidence interval is given by $\hat{p} \pm z \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$. In an attempt to reduce some of the bias as a result of the Wald method, the Agresti–Coull method modifies the estimate of p to be $\tilde{p} = \frac{x + \frac{1}{2}z^2}{n + z^2}$ and modifies the calculation of the confidence interval such that it is given by $\tilde{p} \pm z \sqrt{\frac{\tilde{p}(1-\tilde{p})}{n + z^2}}$.

Finally, the Arcsine method calculates the confidence interval through the use of the equation:

$$\text{Sin}^2 \left(\arcsin \left(\sqrt{\hat{p}} \right) \pm \frac{z}{2\sqrt{n}} \right).$$

Visualization

When visualizing the binomial distribution, a histogram like that shown in Figure 1 is constructed for each specific example. Number of successes, X , is plotted along the x -axis, while the probability of X is plotted along the y -axis according to the probability mass function results. As n increases, the binomial distribution

Figure 1 Binomial Distribution of Baseball Outcomes

will begin to look smoother. However, the binomial distribution does not have a set shape, as p and q change the mean of the distribution, and n , p , and q change the variance of the distribution. When n is large and p approaches $.5$, the binomial distribution approaches a bell-shaped curve. When p is smaller than $.5$, the visualization of the binomial distribution is right skewed. As p becomes smaller, the distribution becomes even more right skewed. When p is larger than $.5$, the visualization of the binomial distribution is left skewed. Again, as p becomes larger, the distribution is even more left skewed.

Examples

Example 1 shows an application of the binomial distribution using the probability mass function. Example 2 shows an application of the binomial distribution using the cumulative distribution function.

Example 1: Baseball Batting Percentage

One example of applying the binomial distribution can be seen by predicting the number of hits a baseball player will get in three at bats. A batting average is calculated by taking the number of times a player has gotten a hit divided by the number of times they have been at bat, minus the number of times they took a base on balls. So a batter’s probability of succeeding in getting a hit, p , can be represented by their batting average, usually somewhere around $p = .3$, and their probability of failing and getting an out, q , can be 1 minus batting average: $q = .7$. In three at bats, there are eight different patterns of outcomes. With a hit represented as “H” and an out repre-

Table 1 Probability for All Possible Patterns of at Bat Outcomes

Outcome	Probability	X
HHH	$.3^3$	3
HHO	$.3^2 \cdot .7$	2
HOH	$.3^2 \cdot .7$	2
HOO	$.3 \cdot .7^2$	1
OHH	$.3^2 \cdot .7$	2
OHO	$.3 \cdot .7^2$	1
OOH	$.3 \cdot .7^2$	1
OOO	$.7^3$	0

sented at “O,” the possible outcomes include HHH, HHO, HOH, HOO, OHH, OHO, OOH, and OOO. However, each of these outcomes has its own probability of happening. To calculate the probability of a pattern, the probability of each individual event is multiplied. So, for example, the probability of HOH would be $.3 \times .7 \times .3$, which can be simplified to $.3^2 \times .7$. Table 1 provides the probabilities for all possible patterns of outcomes.

As Table 1 shows, one combination results in three hits, $X = 3$; three combinations result in two hits and one out, $X = 2$; three combinations result in one hit and two outs, $X = 1$; and one combination results in three outs, $X = 0$. Notice that each pattern that results in the same X value has the same probability value, regardless of what order the hits or outs happen in. This is precisely why the binomial coefficient is included in the probability mass function. Most of the time, a researcher would not ask what the probability of a certain pattern is; instead, a researcher would ask something like “what is the probability that the player gets two hits in three at bats.” In this example, it was fairly easy to calculate the probability of every possible pattern. However, that is not possible in most models, so the binomial coefficient calculates how many patterns result in the same number of successes or the same X value. Table 2 illustrates the frequency table for each X number of successes. The histogram shown in Figure 1 represents this example.

Example 2: Marathon Entry Percentage

Other applications of the binomial distribution need to use the cumulative distribution function rather than the probability mass function. For example, 70% of people who apply to run a local marathon are randomly drawn to receive entry into the race. If five friends all apply, what is the probability that at least four of them

Table 2 Frequency Table of Number of Successes in Three at Bats

X	$f(x)$
0	$.7^3 = .343$
1	$3(.3 \cdot .7^2) = .441$
2	$3(.3^2 \cdot .7) = .189$
3	$.3^3 = .027$

are accepted? In this case, at least four runners means that the probabilities of having 4 of 5 and 5 of 5 admitted need to be summed. So the cumulative distribution function would be

$$P(C \geq 4) = \sum_{i=4}^5 C_i^5 \cdot .7^i \cdot .3^{5-i},$$

$$P(C \geq 4) = C_4^5 \cdot .7^4 \cdot .3^{5-4} + C_5^5 \cdot .7^5 \cdot .3^{5-5},$$

$$P(C \geq 4) = \left(\frac{5!}{4!1!} (.2401)(.3) \right) + \left(\frac{5!}{5!0!} (.16807)(1) \right),$$

$$P(C \geq 4) = .52822.$$

Thus, the probability of at least four of the runners being admitted is approximately .52822 or 52.82%.

BIOLOGICAL AND TECHNICAL REPLICATES

Biological and technical replicates are two different approaches to making repeated measurements of an underlying biological phenomenon in biomedical research. It is generally a good practice to include both types of replicates in each experiment.

Broadly speaking, technical replicates are independently repeated measurements of the same sample using the same procedure. As such, these replicates represent independent measures of the noise (typically random) associated with protocols or equipment: They help measure the reproducibility of an assay and not the reproducibility of the underlying biological phenomenon. Biological replicates, on the other hand, are parallel measurements of biologically distinct samples. These replicates help capture the variation (random or otherwise) of the biological phenomenon under study and help measure its reproducibility. The distinction between technical and biological replicates is a *functional* one, in that it depends on which type of data variability—procedural or biological—they capture and not necessarily on how the replicates are obtained.

There is no one-size-fits-all formula for designing replicates that are optimal for a given experiment. The optimal design, including the optimal mix of technical and biological replicates in a given experiment, depends on the potential sources and magnitudes of variability in a given experiment and the questions that the experiment seeks to answer.

Historical Origins of the Replicate Nomenclature

Until the 1990s, much of the reproducibility testing in biomedical research, especially in the *wet laboratory* experimental sciences such as molecular and cellular biology, employed what would be considered technical replicates today. The push to systematically include biological replicates in experiments originated primarily in these fields in the 2000s with the widespread realization that biomedical research findings were not sufficiently

reproducible, in large part because technical replicates by themselves did not properly account for the variability of the underlying biological phenomena. Major funding agencies in these fields, such as the U.S. National Institutes of Health, spurred the widespread adoption of the current replicate nomenclature and practices of replicate design by incentivizing researchers to employ both biological and technical replicates in their research as a way of enhancing the reproducibility of the research findings.

While the practice of quantitative measurements and statistical testing was much better established in many other fields of biomedical research, such as epidemiology, psychophysics, ecology and evolutionary biology, reproducibility of results was not necessarily commensurately better in these fields, arguably also because of poor replicate design.

Reproducibility Requires Representative Replicates

Research is primarily about learning general truths about the phenomenon under study. A set of findings is useful only to the extent that the same findings are obtained when the given experiment is independently but precisely repeated. The term *reproducibility* typically means this type of across-experiment reproducibility of the *findings* or *conclusions* and not of the *measurements* on which the conclusions are based. One accepts the mathematical reality that the measurements themselves will not be exactly reproducible from one instance to the next, be it within or across experiments, even as one expects the conclusions to be reproducible.

The only way one can draw reproducible conclusions based on inherently variable measurements is to use sound practices of statistical sampling and, where necessary, statistical testing. To the extent that the empirical measurements are truly representative of the underlying phenomenon, one can have a quantifiable degree of confidence, say 95%, that the conclusions will be reproduced when the experiment is exactly repeated. Thus, the key to obtaining reproducible results is to ensure that replicates as a group adequately represent the relevant statistical properties of the phenomenon of interest. This, in a nutshell, is the goal of replicate design: to ensure that the replicates are representative and that they adequately capture the study-relevant statistical properties, including the variability, of the phenomenon.

In biology, the substrates of phenomena of interest tend to be highly variable. Therefore, ensuring that this biological variability is properly represented in the empirical measurements of a given phenomenon is a necessary and proper way of improving the reproducibility of the findings about the phenomenon. In other

words, it is usually a good idea to include biological replicates in an experiment because the underlying biological substrates are usually variable. It follows from the elementary principles of statistics that the greater the variability of the relevant biological substrates, the larger the number of replicates needed to adequately capture this variability.

Basic Principles of Replicate Design

Consider a simple hypothetical experiment to determine the levels of a blood component called *albumin* in adult Sprague Dawley laboratory rats 24 hours after skin injury. We induce injury in a designated spot, say a hind thigh, using standard procedures in one rat. We draw a vial of blood from this rat 24 hours after the procedure and measure the albumin levels using standard procedures. We repeat this measurement twice more independently using the same vial of blood. These constitute three technical replicates because they measure the reproducibility of the albumin assay (Figure 1A). From the three replicates, we determine the mean and the standard deviation of albumin levels.

Note, however, that these findings apply only to the particular vial of blood. We have no way of evaluating whether the results are likely to be reproducible across additional blood draws from the same mouse because we have not tested any additional blood draws. Obviously, this is not a useful outcome and reflects poor replicate design. To make the results more generalizable, we make

three mutually independent blood draws from this rat and measure the albumin levels in each (Figure 1B). Although the sample size remains the same at three, these technical replicates are better designed because the albumin level estimate is likely to be better reproducible for this mouse.

It is desirable to have our findings apply to all Sprague Dawley rats and not just to the one rat we tested. We therefore repeat the experiment using three different rats, making one measurement each (Figure 1C). These three biological replicates allow us to draw conclusions about the three rats in question. To the extent that these three rats are representative of all Sprague Dawley rats, the results should be reproducible across all rats of this strain when the experiment is exactly repeated.

In general, it is a good practice to include both technical and biological replicates (Figure 1D), since the two types of replicates measure different types of variability in the measurements, as noted earlier.

Additional Observations About Replicate Design

There are a few additional things we always wanted to know about replicate design but our mothers never told us. First, it ultimately does not matter whether a given replicate is designated a technical replicate or a biological replicate, as long as the sources of the replicates are faithfully kept track of. For instance, if we arbitrarily shuffle the replicate designations of one or

Figure 1 A Hypothetical Example That Illustrates the Distinction Between Technical and Biological Replicates

Note: In each case, rat blood is drawn and the concentration of albumin in the blood is measured. In each panel, dotted arrows at the top denote blood draws, and solid arrows at the bottom denote albumin measurements. (A) Repeated measurements from the same blood draw nominally represent technical replicates but reflect poor replicate design. (B) A better design for technical replicates is to make multiple independent blood draws and measure albumin level in each draw. (C) Biological replicates are those in which each blood draw is made from a different selected rat. (D) It is generally a good design practice to include both technical and biological replicates in an experiment and to adjust the relative proportions of the two types of replicates so that the replicates are representative of the phenomenon under study. Of the four replicate designs shown, the one in panel D is likely to yield the most reproducible results, even though the sample size ($n = 3$), and therefore the nominal statistical power, is the same in all cases. Note that statistically desirable values of n tend to be higher than 3 in actual experiments.

more replicates in Figure 1, it will not in any way affect the experimental findings, our observations as to which aspects of the experiments the findings apply to, or the reproducibility of the findings. Indeed, the technical replicates in the earlier example meet some of the criteria of biological replicates, in that they capture some of the *procedural* variability with a *biological* basis, such as the variability in the induced injury across rats. In some cases, it can be difficult to decide whether a given replicate qualifies as either type of replicate or both. For instance, what constitutes a technical replicate in a study that seeks to determine whether home value appraisers estimate lower values for homes owned by African Americans than those owned by Caucasians? Moreover, there are vast areas of research where the phenomena of interest are not biological at all. For instance, what would constitute biological replicates in a study about the effect of ethanol on catalytic converters in cars? Yet, no one would dispute the importance of these research questions or of ensuring the reproducibility of the findings by designing the replicates properly. In thinking about these issues, it helps to keep in mind the aforementioned historical origins of the replicate nomenclature and that while reproducibility is desirable in all research, not all research involves biology or even experimentation.

Second, proper replicate design requires that the goals of the study and the planned data analyses be precisely specified beforehand. This is especially important when the underlying phenomena are complex, multivariate, and/or subject to dynamic change. For instance, in the case of the aforementioned rat experiment, we need to decide which aspects of the underlying phenomenon we want to draw conclusions about and how broadly we want to draw them: injury to which body regions, which types of the injury (e.g., abrasions, cuts, chemicals, or burns), which ages, and so forth. Specifying the research question has the effect of specifying which statistical properties are relevant to the study and which are not, thus making replicate design more tractable. Without specifying the study parameters in this fashion, we would risk either having to obtain an unmanageably large number of replicates to try and capture all potential statistical variability of the underlying substrates or designing poor replicates that fail to capture the study-relevant variations of the phenomenon, and thereby reducing the reproducibility of the research findings. Specifying the planned tests is necessary for, among other things, planning the number of various replicates. For instance, in the aforementioned rat experiment, we planned no statistical tests because the goal of this simple experiment was to simply estimate the albumin levels, not to test any hypotheses. For a more complex experiment, in which we test the hypothesis that albumin levels in rats with skin injury are higher than in

control rats that underwent a sham procedure, we would need to obtain replicates from both the treatment group and control group of rats. The numbers of the replicates do not necessarily have to be the same between the two groups. For instance, sham injury may be quite consistent from one rat to the next, so that fewer technical replicates might suffice for the control group.

Third, replicate design is closely related to, but not the same as, sample size calculation. A common, recommended practice is to first perform power analyses based on the expected strength of the effect under study (estimated based on the best available information from published results or pilot data), planned statistical tests, and the desired level of statistical significance and statistical power. This will yield the required total number of replicates (or sample size n). The n value can then be broken down into the desired numbers of technical versus biological replicates based on the estimated variability from various sources.

A fourth, related principle is that it is the responsibility of the researcher to report the replicate design, along with the rest of the study methods in sufficient detail as to enable other researchers to replicate the findings independently. Reporting a study poorly is tantamount to designing it poorly.

Finally, there are many cases in which a statistically optimal replicate design is not possible, not desirable, or both. For instance, in invasive studies of neural activity in monkey brains, it is typical to use only two monkeys because using additional monkeys is inadvisable without a compelling reason. Instead, researchers typically study a large number of individual neurons in either monkey, which results in a statistically suboptimal nested replicate design. One can nonetheless draw the best possible reproducible conclusions from such nested data using commonly available statistical tools. In cases such as this, the imperatives of sound statistical design must be balanced against other principles of sound research, and reproducibility must be maximized using the best available alternative methods.

BIVARIATE REGRESSION

Regression is a statistical technique used to help investigate how variation in one or more variables predicts or explains variation in another variable. This popular statistical technique is flexible in that it can be used to analyze experimental or nonexperimental data with multiple categorical and continuous independent variables. If only one variable is used to predict or explain the variation in another variable, the technique is referred to as *bivariate regression*. When more than one variable is used to predict or explain variation in another variable, the technique is referred to as *multiple regression*. Bivariate regression is the focus of this entry.

Various terms are used to describe the independent variable in regression, namely, *predictor variable*, *explanatory variable*, or *presumed cause*. The dependent variable is often referred to as an *outcome variable*, *criterion variable*, or *presumed effect*. The choice of independent variable term will likely depend on the preference of the researcher or the purpose of the research. Bivariate regression may be used solely for predictive purposes. For example, do scores on a college entrance exam predict college grade point average? Or it may be used for explanation. Do differences in IQ scores explain differences in achievement scores? It is often the case that although the term *predictor* is used by researchers, the purpose of the research is, in fact, explanatory.

Suppose a researcher is interested in how well reading in first grade predicts or explains fifth-grade science achievement scores. The researcher hypothesizes that those who read well in first grade will also have high science achievement in fifth grade. An example bivariate regression will be performed to test this hypothesis. The data used in this example are a random sample of students (10%) with first-grade reading and fifth-grade science scores and are taken from the Early Childhood Longitudinal Study public database. Variation in reading scores will be used to explain variation in science

achievement scores, so first-grade reading achievement is the explanatory variable and fifth-grade science achievement is the outcome variable. Before the analysis is conducted, however, it should be noted that bivariate regression is rarely used in published research. For example, intelligence is likely an important common cause of both reading and science achievement. If a researcher was interested in explaining fifth-grade science achievement, then potential important common causes, such as intelligence, would need to be included in the research.

Regression Equation

The simple equation for bivariate linear regression is $Y = a + bX + e$. The science achievement score, Y , for a student equals the intercept or constant (a), plus the slope (b) times the reading score (X) for that student, plus error (e). Error, or the residual component (e), represents the error in prediction, or what is not explained in the outcome variable. The error term is not necessary and may be dropped so that the following equation is used: $Y' = a + bX$. Y' is the expected (or predicted) score. The intercept is the predicted fifth-grade science score for someone whose first-grade reading score is zero. The slope (b , also referred to as the *unstandardized regression coefficient*) represents the predicted unit increase in science scores associated with a one-unit increase in reading scores. X is the observed score for that person. The two parameters (a and b) that describe the linear relation between the predictor and outcome are thus the intercept and the regression coefficient. These parameters are often referred to as least squares estimators and will be estimated using the two sets of scores. That is, they represent the optimal estimates that will provide the least error in prediction.

Returning to the example, the data used in the analysis were first-grade reading scores and fifth-grade science scores obtained from a sample of 1,027 school-age children. T -scores, which have a mean of 50 and standard deviation of 10, were used. The means for the scores in the sample were 51.31 for reading and 51.83 for science.

Because science scores are the outcome, the science scores are regressed on first-grade reading scores. The easiest way to conduct such analysis is to use a statistical program. The estimates from the output may then be plugged into the equation. For these data, the prediction equation is $Y' = 21.99 + (.58)X$. Therefore, if a student's first-grade reading score was 60, the predicted fifth-grade science achievement score for that student would be $21.99 + (.58)60$, which equals 56.79. One might ask, why even conduct a regression analysis to obtain a predicted science score when Johnny's science score was already available? There are a few possible reasons.

First, perhaps a researcher wants to use the information to predict later science performance, either for a new group of students or for an individual student, based on current first-grade reading scores. Second, a researcher may want to know the relation between the two variables, and a regression provides a nice summary of the relation between the scores for all the students. For example, do those students who tend to do well in reading in first grade also do well in science in fifth grade? Last, a researcher might be interested in different outcomes related to early reading ability when considering the possibility of implementing an early reading intervention program. Of course a bivariate relation is not very informative. A much more thoughtfully developed causal model would need to be developed if a researcher was serious about this type of research.

Scatterplot and Regression Line

The regression equation describes the linear relation between variables; more specifically, it describes science scores as a function of reading scores. A scatterplot could be used to represent the relation between these two variables, and the use of a scatterplot may assist one in understanding regression. In a scatterplot, the science scores (outcome variable) are on the y -axis, and the reading scores (explanatory variable) are on the x -axis.

A scatterplot is shown in Figure 1. Each person's reading and science scores in the sample are plotted. The scores are clustered fairly closely together, and the

general direction looks to be positive. Higher scores in reading are generally associated with higher scores in science. The next step is to fit a regression line. The regression line is plotted so that it minimizes errors in prediction, or simply, the regression line is the line that is closest to all the data points. The line is fitted automatically in many computer programs, but information obtained in the regression analysis output can also be used to plot two data points that the line should be drawn through. For example, the intercept (where the line crosses the y -axis) represents the predicted science score when reading equals zero. Because the value of the intercept was 21.99, the first data point would be found at 0 on the x -axis and at 21.99 on the y -axis. The second point on the line may be located at the mean reading score (51.31) and mean science score (51.83). A line can then be drawn through those two points. The line is shown in Figure 1. Points that are found along this regression line represent the predicted science achievement score for Person A with a reading score of X .

Unstandardized and Standardized Coefficients

For a more thorough understanding of bivariate regression, it is useful to examine in more detail the output obtained after running the regression. First, the intercept has no important substantive meaning. It is unlikely that anyone would score a zero on the reading test, so it does not make much sense. It is useful in the unstandardized solution in that it is used to obtain predicted scores (it is

Figure 1 Scatterplot and Regression Line

a constant value added to everyone's score), and as demonstrated above, it is useful in plotting a regression line. The slope ($b = .58$) is the unstandardized coefficient. It was statistically significant, indicating that reading has a statistically significant influence on fifth-grade science. A 1-point T -score increase in reading is associated with a .58 T -score point increase in science scores. The b s are interpreted in the metric of the original variable. In the example, all the scores were T -scores. Unstandardized coefficients are especially useful for interpretation when the metric of the variables is meaningful. Sometimes, however, the metric of the variables is not meaningful.

Two equations were generated in the regression analysis. The first, as discussed in the example above, is referred to as the *unstandardized solution*. In addition to the unstandardized solution, there is a *standardized solution*. In this equation, the constant is dropped, and z scores (mean = 0, standard deviation = 1), rather than the T -scores (or raw scores), are used. The standardized regression coefficient is referred to as a *beta weight* (β). In the example, the beta weight was .56. Therefore, a one-standard-deviation increase in reading was associated with a .56-standard-deviation increase in science achievement. The unstandardized and standardized coefficients were similar in this example because T -scores are standardized scores, and the sample statistics for the T -scores were fairly close to the population mean of 50 and standard deviation of 10.

It is easy to convert back and forth from standardized to unstandardized regression coefficients:

$$\beta = b \left(\frac{\text{standard deviation of reading scores}}{\text{standard deviation of science scores}} \right)$$

or

$$b = \beta \left(\frac{\text{standard deviation of science scores}}{\text{standard deviation of reading scores}} \right).$$

From an interpretative standpoint, should someone interpret the unstandardized or the standardized coefficient? There is some debate over which one to use for interpretative statements, but in a bivariate regression, the easiest answer is that if both variables are in metrics that are easily interpretable, then it would make sense to use the unstandardized coefficients. If the metrics are not meaningful, then it may make more sense to use the standardized coefficient. Take, for example, number of books read per week. If number of books read per week was represented by the actual number of books read per week, the variable is in a meaningful metric. If the number of books read per week variable were coded so that 0 = no books read per week, 1 = one to three books read per week, and 2 = four or more books read per week, then the variable is not coded in a meaningful metric, and the stan-

dardized coefficient would be the better one to use for interpretation.

R and R^2

In bivariate regression, typically the regression coefficient is of greatest interest. Additional information is provided in the output, however. R is used in multiple regression output and represents a multiple correlation. Because there is only one explanatory variable, R (.56) is equal to the correlation coefficient ($r = .56$) between reading and science scores. Note that this value is also identical to the β . Although the values of β and r are the same, the interpretation differs. The researcher is not proposing an agnostic relation between reading scores and science scores. Rather the researcher is positing that early reading explains later science achievement. Hence, there is a clear direction in the relation, and this direction is not specified in a correlation.

R^2 is the variance in science scores explained by reading scores. In the current example, $R^2 = .31$. First-grade reading scores explained 31% of the variance in fifth-grade science achievement scores.

Statistical Significance

R and R^2 are typically used to evaluate the statistical significance of the overall regression equation (the tests for the two will result in the same answer). The null hypothesis is that R^2 equals zero in the population. One way of calculating the statistical significance of the overall regression is to use an F test associated with the value obtained with the formula

$$\frac{R^2 / k}{(1 - R^2) / (N - k - 1)}.$$

In this formula, R^2 equals the variance explained, $1 - R^2$ is the variance unexplained, and k equals the degrees of freedom (df) for the regression (which is 1 because one explanatory variable was used). With the numbers plugged in, the formula would look like

$$\frac{.31 / 1}{.69 / (1027 - 1 - 1)}$$

and results in $F = 462.17$. An F table indicates that reading did have a statistically significant effect on science achievement, $R^2 = .31$, $F(1, 1025) = 462.17$, $p < .01$.

In standard multiple regression, a researcher typically interprets the statistical significance of R^2 (the statistical significance of the overall equation) and the statistical significance of the unique effects of each individual explanatory variable. Because this is bivariate regression, however, the statistical significance test of

the overall regression and the regression coefficient (b) will yield the same results, and typically the statistical significance tests for each are not reported.

The statistical significance of the regression coefficient (b) is evaluated with a t test. The null hypothesis is that the slope equals zero, that is, the regression line is parallel with the x -axis. The t -value is obtained by

$$\frac{b}{\text{standard error of } b}.$$

In this example, $b = .58$, and its associated standard error was .027. The t -value was 21.50. A t -table could be consulted to determine whether 21.50 is statistically significant. Or a rule of thumb may be used that given the large sample size and with a two-tailed significance test, a t -value greater than 2 will be statistically significant at the $p < .05$ level. Clearly, the regression coefficient was statistically significant. Earlier it was mentioned that because this is a bivariate regression, the significance of the overall regression and b provide redundant information. The use of F and t tests may thus be confusing, but note that F (462.17) equals t^2 (21.50²) in this bivariate case. A word of caution: This finding does not generalize to multiple regression. In fact, in a multiple regression, the overall regression might be significant, and some of the b s may or may not be significant. In a multiple regression, both the overall regression equation and the individual coefficients are examined for statistical significance.

Residuals

Before completing this explanation of bivariate regression, it will be instructive to discuss a topic that has been for the most part avoided until now: the residuals. Earlier it was mentioned that e (residual) was also included in the regression equation. Remember that regression parameter estimates minimize the prediction errors, but the prediction is unlikely to be perfect. The residuals represent the error in prediction. Or the residual variance represents the variance that is left unexplained by the explanatory variable. Returning to the example, if reading scores were used to predict science scores for those 1,026 students, each student would have a prediction equation in which his or her reading score would be used to calculate a predicted science score. Because the actual score for each person is also known, the residual for each person would represent the observed fifth-grade science score minus the predicted score obtained from the regression equation. Residuals are thus observed scores minus predicted scores, or conceptually they may be thought of as the fifth-grade science scores with effects of first-grade reading removed.

Another way to think of the residuals is to revert back to the scatterplot in Figure 1. The x -axis represents the observed scores, and the y -axis represents the science scores. Both predicted and actual scores are already plotted on this scatterplot. That is, the predicted scores are found on the regression line. If a person's reading score was 40, the predicted science score may be obtained by first finding 40 on the x -axis, and then moving up in a straight line until reaching the regression line. The observed science scores for this sample are also shown on the plot, represented by the dots scattered about the regression line. Some are very close to the line whereas others are farther away. Each person's residual is thus represented by the distance between the observed score and the regression line. Because the regression line represents the predicted scores, the residuals are the difference between predicted and observed scores. Again, the regression line minimizes the distance of these residuals from the regression line. Much as residuals are thought of as science scores with the effects of reading scores removed, the residual variance is the proportion of variance in science scores left unexplained by reading scores. In the example, the residual variance was .69, or $1 - R^2$.

Regression Interpretation

An example interpretation for the reading and science example concludes this entry on bivariate regression. The purpose of this study was to determine how well first-grade science scores explained fifth-grade science achievement scores. The regression of fifth-grade science scores on first-grade reading scores was statistically significant, $R^2 = .31$, $F(1,1025) = 462.17$, $p < .01$. Reading accounted for 31% of the variance in science achievement. The unstandardized regression coefficient was .58, meaning that for each T -score point increase in reading, there was a .58 T -score increase in science achievement. Children who are better readers in first grade also tend to be higher achievers in fifth-grade science.

BLOCK DESIGN

Sir Ronald Fisher, the father of modern experimental design, extolled the advantages of block designs in his classic book, *The Design of Experiments*. He observed that block designs enable researchers to reduce error variation and thereby obtain more powerful tests of false null hypotheses. In the behavioral sciences, a significant source of error variation is the nuisance variable of individual differences. This nuisance variable can be isolated by assigning participants or experimental units to blocks so that at the beginning of an experiment, the participants within a block are more homogeneous with respect to the dependent variable than are participants in different blocks. Three procedures are used to form homogeneous blocks.

1. Match participants on a variable that is correlated with the dependent variable. Each block consists of a set of matched participants.
2. Observe each participant under all or a portion of the treatment levels or treatment combinations. Each block consists of a single participant who is observed two or more times. Depending on the nature of the treatment, a period of time between treatment level administrations may be necessary in order for the effects of one treatment level to dissipate before the participant is observed under other levels.
3. Use identical twins or litter mates. Each block consists of participants who have identical or similar genetic characteristics.

Block designs also can be used to isolate other nuisance variables, such as the effects of administering treatments at different times of day, on different days of the week, or in different testing facilities. The salient features of the five most often used block designs are described next.

Block Designs With One Treatment

Dependent Samples *t*-Statistic Design

The simplest block design is the randomization and analysis plan that is used with a *t* statistic for dependent

samples. Consider an experiment to compare two ways of memorizing Spanish vocabulary. The dependent variable is the number of trials required to learn the vocabulary list to the criterion of three correct recitations. The null and alternative hypotheses for the experiment are, respectively,

$$H_0: \mu_1 - \mu_2 = 0$$

and

$$H_1: \mu_1 - \mu_2 \neq 0,$$

where μ_1 and μ_2 denote the population means for the two memorization approaches. It is reasonable to believe that IQ is negatively correlated with the number of trials required to memorize Spanish vocabulary. To isolate this nuisance variable, n blocks of participants can be formed so that the two participants in each block have similar IQs. A simple way to form blocks of matched participants is to rank the participants in terms of IQ. The participants ranked 1 and 2 are assigned to Block 1, those ranked 3 and 4 are assigned to Block 2, and so on. Suppose that 20 participants have volunteered for the memorization experiment. In this case, $n = 10$ blocks of dependent samples can be formed. The two participants in each block are randomly assigned to the memorization approaches. The layout for the experiment is shown in Figure 1.

The null hypothesis is tested using a *t* statistic for dependent samples. If the researcher's hunch is correct—that IQ is correlated with the number of trials to learn—the design should result in a more powerful test of a false null hypothesis than would a *t*-statistic design for

	<i>Treat.</i> <i>Level</i>	<i>Dep.</i> <i>Var.</i>	<i>Treat.</i> <i>Level</i>	<i>Dep.</i> <i>Var.</i>

		$\bar{Y}_{.1}$	$\bar{Y}_{.2}$	

Figure 1 Layout for a Dependent Samples *t*-Statistic Design

Note: a_j denotes a treatment level (*Treat. Level*); Y_{ij} denotes a measure of the dependent variable (*Dep. Var.*). Each block in the memorization experiment contains two matched participants. The participants in each block are randomly assigned to the treatment levels. The means of the treatments levels are denoted by $\bar{Y}_{.1}$ and $\bar{Y}_{.2}$.

independent samples. The increased power results from isolating the nuisance variable of IQ so that it does not appear in the estimates of the error effects.

Randomized Block Design

The randomized block analysis of variance design can be thought of as an extension of a dependent samples *t*-statistic design for the case in which the treatment has two or more levels. The layout for a randomized block design with $p = 3$ levels of Treatment A and $n = 10$ blocks is shown in Figure 2. A comparison of this layout with that in Figure 1 for the dependent samples *t*-statistic design reveals that the layouts are the same except that the randomized block design has three treatment levels.

In a randomized block design, a block might contain a single participant who is observed under all p treatment levels or p participants who are similar with respect to a variable that is correlated with the dependent variable. If each block contains one participant, the order in which the treatment levels are administered is randomized independently for each block, assuming that the nature of the research hypothesis permits this. If a block contains p matched participants, the participants in each block are randomly assigned to the treatment levels.

The statistical analysis of the data is the same whether repeated measures or matched participants are used. However, the procedure used to form homogeneous blocks does affect the interpretation of the results. The results of an experiment with repeated measures generalize to a population of participants who have been exposed to all the treatment levels. The results of an experiment with matched participants generalize to a population of participants who have been exposed to only one treatment level.

The total sum of squares (SS) and total degrees of freedom for a randomized block design are partitioned as follows:

$$SSTOTAL = SSA + SSBLOCKS + SSRESIDUAL$$

$$np - 1 = (p - 1) + (n - 1) + (n - 1)(p - 1),$$

where SSA denotes the Treatment A SS and $SSBLOCKS$ denotes the blocks SS. The $SSRESIDUAL$ is the interaction between Treatment A and blocks; it is used to estimate error effects. Many test statistics can be thought of as a ratio of error effects and treatment effects as follows:

$$\text{Test statistic} = \frac{f(\text{error effects}) + f(\text{treatment effects})}{f(\text{error effects})},$$

where $f()$ denotes a function of the effects in parentheses. The use of a block design enables a researcher to isolate variation attributable to the blocks variable so that it does not appear in estimates of error effects. By removing this nuisance variable from the numerator and denominator of the test statistic, a researcher is rewarded with a more powerful test of a false null hypothesis.

Two null hypotheses can be tested in a randomized block design. One hypothesis concerns the equality of the Treatment A population means; the other hypothesis concerns the equality of the blocks population means. For this design and those described later, assume that the treatment represents a fixed effect and the nuisance variable, blocks, represents a random effect. For this mixed model, the null hypotheses are

	Treat. Level	Dep. Var.	Treat. Level	Dep. Var.	Treat. Level	Dep. Var.	
Block 1	a_1	Y_{11}	a_2	Y_{12}	a_3	Y_{13}	$\bar{Y}_1.$
Block 2	a_1	Y_{21}	a_2	Y_{22}	a_3	Y_{23}	$\bar{Y}_2.$
Block 3	a_1	Y_{31}	a_2	Y_{32}	a_3	Y_{33}	$\bar{Y}_3.$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
Block 10	a_1	$Y_{10, 1}$	a_2	$Y_{10, 2}$	a_3	$Y_{10, 3}$	$\bar{Y}_{10}.$
		$\bar{Y}_{.1}$			$\bar{Y}_{.2}$	$\bar{Y}_{.3}$	

Figure 2 Layout for a Randomized Block Design With $p = 3$ Treatment Levels and $n = 10$ Blocks

Note: a_i denotes a treatment level (Treat. Level); Y_{ij} denotes a measure of the dependent variable (Dep. Var.). Each block contains three matched participants. The participants in each block are randomly assigned to the treatment levels. The means of Treatment A are denoted by $\bar{Y}_{.1}$ and $\bar{Y}_{.2}$ and $\bar{Y}_{.3}$ and the means of the blocks are denoted by $\bar{Y}_1., \dots, \bar{Y}_{10}.$

$$H_0: \mu_{.1} = \mu_{.2} = \dots = \mu_{.p}$$

(treatment A population means are equal)

$$H_0: \sigma_{BL}^2 = 0$$

(variance of the blocks, BL, population means is equal to zero)

where μ_{ij} denotes the population mean for the i th block and the j th level of treatment A.

The F statistics for testing these hypotheses are

$$F = \frac{SSA / (p-1)}{SSRESIDUAL / [(n-1)(p-1)]}$$

$$= \frac{MSA}{MSRESIDUAL}$$

and

$$F = \frac{SSBL / (n-1)}{SSRESIDUAL / [(n-1)(p-1)]}$$

$$= \frac{MSBL}{MSRESIDUAL}.$$

The test of the blocks null hypothesis is generally of little interest because the population means of the nuisance variable are expected to differ.

The advantages of the design are simplicity in the statistical analysis and the ability to isolate a nuisance variable so as to obtain greater power to reject a false null hypothesis. The disadvantages of the design include the difficulty of forming homogeneous blocks and of observing participants p times when p is large and the restrictive sphericity assumption of the design. This assumption states that in order for F statistics to be distributed as central F when the null hypothesis is true, the variances of the differences for all pairs of treatment levels must be homogeneous; that is,

$$\sigma_{Y_i - Y_{j'}}^2 = \sigma_j^2 + \sigma_{j'}^2 - 2\sigma_{jj'}, \text{ for all } j \text{ and } j'.$$

Generalized Randomized Block Design

A generalized randomized block design is a variation of a randomized block design. Instead of having n blocks of p homogeneous participants, the generalized randomized block design has w groups of np homogeneous participants. The w groups, like the n blocks in a randomized

Figure 4 Layout for a Two-Treatment, Randomized Block Factorial Design in Which Four Homogeneous Participants Are Randomly Assigned to the $pq = 2 \times 2 = 4$ Treatment Combinations in Each Block

Note: a_jb_k denotes a treatment combination (Treat. Comb.); Y_{ijk} denotes a measure of the dependent variable (Dep. Var.).

block design, represent a nuisance variable that a researcher wants to remove from the error effects. The generalized randomized block design can be used when a researcher is interested in one treatment with $p \geq 2$ treatment levels and the researcher has sufficient participants to form w groups, each containing np homogeneous participants. The total number of participants in the design is $N = npw$. The layout for the design is shown in Figure 3.

In the memorization experiment described earlier, suppose that 30 volunteers are available. The 30 participants are ranked with respect to IQ. The $np = (2)(3) = 6$ participants with the highest IQs are assigned to Group 1, the next 6 participants are assigned to Group 2, and so on. The $np = 6$ participants in each group are then randomly assigned to the $p = 3$ treatment levels with the restriction that $n = 2$ participants are assigned to each level.

The total SS and total degrees of freedom are partitioned as follows:

$$SSTOTAL = SSA + SSG + SSA \times G + SSWCELL$$

$$npw - 1 = (p - 1) + (w - 1) + (p - 1)(w - 1) + pw(n - 1),$$

where SSG denotes the groups SS and $SSA \times G$ denotes the interaction of Treatment A and groups. The within-cells SS, $SSWCELL$, is used to estimate error effects. Three null hypotheses can be tested:

1. $H_0 : \mu_{1.} = \mu_{2.} = \dots = \mu_p$
(Treatment A population means are equal),
2. $H_0 : \sigma_G^2 = 0$
(variance of the groups, G, population means is equal to zero),
3. $H_0 : \sigma_{A \times G}^2 = 0$
(variance of the $A \times G$ interaction is equal to zero),

where μ_{jz} denotes a population mean for the i th participant in the j th treatment level and z th group. The three null hypotheses are tested using the following F statistics:

$$1. F = \frac{SSA / (p - 1)}{SSWCELL / [pw(n - 1)]} = \frac{MSA}{MSWCELL},$$

$$2. F = \frac{SSG / (w - 1)}{SSWCELL / [pw(n - 1)]} = \frac{MSG}{MSWCELL},$$

$$3. F = \frac{SSA \times G / (p - 1)(w - 1)}{SSWCELL / [pw(n - 1)]} = \frac{MSA \times G}{MSWCELL}$$

The generalized randomized block design enables a researcher to isolate one nuisance variable—an advantage that it shares with the randomized block design. Furthermore, the design uses the within-cell variation in the $pw = (3)(5) = 15$ cells to estimate error effects rather than an interaction, as in the randomized block design. Hence, the restrictive sphericity assumption of the randomized block design is replaced with the assumption of homogeneity of within-cell population variances.

Block Designs With Two or More Treatments

The blocking procedure that is used with a randomized block design can be extended to experiments that have two or more treatments, denoted by the letters A, B, C, and so on.

Randomized Block Factorial Design

A randomized block factorial design with two treatments, denoted by A and B, is constructed by crossing the p levels of Treatment A with the q levels of

Treatment B . The design's n blocks each contain $p \times q$ treatment combinations: $a_1b_1, a_1b_2 \dots a_pb_q$. The design enables a researcher to isolate variation attributable to one nuisance variable while simultaneously evaluating two treatments and associated interaction.

The layout for the design with $p=2$ levels of Treatment A and $q=2$ levels of Treatment B is shown in Figure 4. It is apparent from Figure 4 that all the participants are used in simultaneously evaluating the effects of each treatment. Hence, the design permits efficient use of resources because each treatment is evaluated with the same precision as if the entire experiment had been devoted to that treatment alone.

The total SS and total degrees of freedom for a two-treatment randomized block factorial design are partitioned as follows:

$$\begin{aligned} SSTOTAL &= SSBL + SSA + SSB \\ npq - 1 &= (n-1) + (p-1) + (q-1) \\ &+ SSA \times B + SSRESIDUAL \\ &+ (p-1)(q-1) + (n-1)(pq-1). \end{aligned}$$

Four null hypotheses can be tested:

1. $H_0: \sigma_{BL}^2 = 0$ (variance of the blocks, BL , population means is equal to zero),
2. $H_0: \mu_{.1} = \mu_{.2} = \dots = \mu_{.p}$ (Treatment A population means are equal),
3. $H_0: \mu_{.1} = \mu_{.2} = \dots = \mu_{.q}$ (Treatment B population means are equal),
4. $H_0: A \times B$ interaction = 0 (Treatments A and B do not interact),

where μ_{ijk} denotes a population mean for the i th block, j th level of Treatment A , and k th level of treatment B . The F statistics for testing the null hypotheses are as follows:

$$\begin{aligned} F &= \frac{SSBL / (n-1)}{SSRESIDUAL / [(n-1)(pq-1)]} \\ &= \frac{MSBL}{MSRESIDUAL}, \end{aligned}$$

$$\begin{aligned} F &= \frac{SSA / (p-1)}{SSRESIDUAL / [(n-1)(pq-1)]} \\ &= \frac{MSA}{MSRESIDUAL}, \end{aligned}$$

$$\begin{aligned} F &= \frac{SSB / (q-1)}{SSRESIDUAL / [(n-1)(pq-1)]} \\ &= \frac{MSB}{MSRESIDUAL}, \end{aligned}$$

$$\begin{aligned} F &= \frac{SSA \times B / (p-1)(q-1)}{SSRESIDUAL / [(n-1)(pq-1)]} \\ &= \frac{MSA \times B}{MSRESIDUAL}. \end{aligned}$$

The design shares the advantages and disadvantages of the randomized block design. Furthermore, the design enables a researcher to efficiently evaluate two or more treatments and associated interactions in the same experiment. Unfortunately, the design lacks simplicity in the interpretation of the results if interaction effects are present. The design has another disadvantage: If Treatment A or B has numerous levels, say four or five, the block size becomes prohibitively large. For example, if $p=4$ and $q=3$, the design has blocks of size $4 \times 3 = 12$. Obtaining n blocks with 12 matched participants or observing n participants on 12 occasions is often not feasible. A design that reduces the size of the blocks is described next.

Split-Plot Factorial Design

In the late 1920s, Fisher and Frank Yates addressed the problem of prohibitively large block sizes by developing confounding schemes in which only a portion of the treatment combinations in an experiment are assigned to each block. The split-plot factorial design achieves a reduction in the block size by confounding one or more treatments with groups of blocks. *Group-treatment confounding* occurs when the effects of, say, Treatment A with p levels are indistinguishable from the effects of p groups of blocks.

The layout for a two-treatment split-plot factorial design is shown in Figure 5. The block size in the split-plot factorial design is half as large as the block size of the randomized block factorial design in Figure 4 although the designs contain the same treatment combinations. Consider the sample means $\bar{Y}_{.1}$ and $\bar{Y}_{.2}$ in Figure 5. Because of confounding, the difference between $\bar{Y}_{.1}$ and $\bar{Y}_{.2}$ reflects both group effects and Treatment A effects.

The total SS and total degrees of freedom for a split-plot factorial design are partitioned as follows:

$$\begin{aligned} SSTOTAL &= SSA + SSBL(A) + SSB \\ &+ SSA \times B + SSRESIDUAL \\ npq - 1 &= (p-1) + p(n-1) + (q-1) \\ &+ (p-1)(q-1) + p(n-1)(q-1), \end{aligned}$$

			<i>Treat.</i> <i>Comb.</i>	<i>Dep.</i> <i>Var.</i>	<i>Treat.</i> <i>Comb.</i>	<i>Dep.</i> <i>Var.</i>

		Block ₁₂	a_2b_1	$Y_{12, 21}$	a_2b_2	$Y_{12, 22}$	
		$\vdots$	$\vdots$	$\vdots$	$\vdots$		
		Block ₂₀	a_2b_1	$Y_{20, 21}$	a_2b_2	$Y_{20, 22}$	
			$\bar{Y}_{\cdot 1}$		$\bar{Y}_{\cdot 2}$		

Figure 5 Layout for a Two-Treatment, Split-Plot Factorial Design in Which 10 + 10 = 20 Homogeneous Blocks Are Randomly Assigned to the Two Groups

Note: a_jb_k denotes a treatment combination (Treat. Comb.); Y_{ijk} denotes a measure of the dependent variable (Dep. Var.). Treatment A is confounded with groups. Treatment B and the $A \times B$ are not confounded.

where $SSBL(A)$ denotes the SS for blocks within Treatment A. Three null hypotheses can be tested:

1. $H_0: \mu_{\cdot 1} = \mu_{\cdot 2} = \dots = \mu_{\cdot p}$ (Treatment A population means are equal),
2. $H_0: \mu_{\cdot 1} = \mu_{\cdot 2} = \dots = \mu_{\cdot q}$ (Treatment B population means are equal),
3. $H_0: A \times B$ interaction = 0 (Treatments A and B do not interact),

where μ_{jk} denotes the j th block, j th level of treatment A, and k th level of treatment B. The F statistics are

$$\begin{aligned}
 F &= \frac{SSA / (p - 1)}{SSBL(A) / [p(n - 1)]} = \frac{MSA}{MSBL(A)}, \\
 F &= \frac{SSB / (q - 1)}{SSRESIDUAL / [p(n - 1)(q - 1)]} \\
 &= \frac{MSB}{MSRESIDUAL}, \\
 F &= \frac{SSA \times B / (p - 1)(q - 1)}{SSRESIDUAL / [p(n - 1)(q - 1)]} \\
 &= \frac{MSA \times B}{MSRESIDUAL}.
 \end{aligned}$$

The split-plot factorial design uses two error terms: $MSBL(A)$ is used to test Treatment A; a different and usually much smaller error term, $MSRESIDUAL$, is used to test Treatment B and the $A \times B$ interaction. Because $MSRESIDUAL$ is generally smaller than $MSBL(A)$, the power of the tests of Treatment B and the $A \times B$ interaction is greater than that for Treatment A.

BLOCKMODELING

Blockmodeling is an approach for partitioning or clustering units (e.g., nodes, vertices, actors) of a network based on patterns (i.e., structure) of their ties to each other. By shrinking the groups that are then obtained, a new network called a *blockmodel* is

Figure 1 From an Unordered Network/Matrix to a Blockmodel

created whereby units represent groups and ties represent ties among these groups. This process is depicted in Figure 1: The right column shows graph representation and the left column shows the matrix representation of the network. Blockmodeling is therefore used to transform a large and complex network into a smaller and more comprehensible one. Blockmodeling has also been used to operationalize social roles.

A More Detailed Description

The term *blockmodeling* arises from the fact that when a network is represented by a matrix, and this matrix is rearranged according to a partition (so that the units that are part of the same groups are located together), blocks that represent ties within and between groups appear if one separates the groups by lines. These blocks are seen in the second *row* of the left column in Figure 1, where nine blocks are visible.

More formally, blockmodeling is an approach for clustering units in a network based on some form of equivalence. Equivalence is something that tells which units can be considered equal in some respect. As units typically are not perfectly equivalent to each other, blockmodeling methods usually attempt to cluster together units that are more equivalent to each other than to other units.

Equivalences

The form of equivalence class that is most commonly used is structural equivalence. Units are structurally equivalent if they are connected in the same way to the same units. If a partition is compatible with structural equivalence—that is, if the units within all the groups are perfectly structurally equivalent—then all ties within each block that are induced by the partition into such groups are all equal. With binary networks, this means that either the induced blocks are null (empty, meaning that no ties are present or, equivalently, that all ties have a value of 0) or they are complete (all possible ties are present or, equivalently, all of the ties have a value of 1).

Similarly, units are regularly equivalent if they are connected in the same way to equivalent others. The definition is circular by design. For binary networks, if a partition is compatible with regular equivalence, then all the blocks induced by that partition are either null or regular. A regular block is a block that has at least one tie in each row and each column. Namely, each unit from a *row* group must be connected to at least one unit from the *column* group.

Generalized equivalence is defined by block types and possibly their position in the blockmodel. Block type defines the allowed pattern of ties within a block. While describing structural and regular equivalence, these patterns are described earlier for binary networks for null, complete, and regular block types, yet numerous block types are defined for both binary and valued networks. Therefore, generalized equivalence is not a single equivalence class, but a way of specifying custom equivalences.

Another frequently used form of equivalence is stochastic equivalence. Units are stochastically equivalent if they have the same probability of having a tie to all other units.

Types of Blockmodeling

Blockmodeling approaches are characterized by several features. One such feature is the kind of networks the approaches are designed to analyze. For example, there are approaches for one-mode networks (all units can connect to any other unit and are of the same type) as well as for two-mode networks (ties are only possible between units of different types). Similarly, there are approaches that can handle either only single-relational networks or also multirelational ones. Certain approaches can also handle temporal or multilevel networks. Still pertaining to the type of networks, some approaches can handle only binary networks, while others can handle signed (where negative ties are also possible) or values networks (where ties can also have other values beyond simply 0 or 1).

Other divisions are based on the underlying characteristics of the algorithm being used. An important distinction is between stochastic and deterministic blockmodeling. Stochastic blockmodeling approaches are essentially those based on stochastic equivalence. They rely on some probabilistic model or generative model of network formation. Similar models also go by the name of mixture models for block clustering.

In contrast, deterministic approaches are not based on such a model and can be split into direct and indirect methods. Indirect methods involve two steps. First, a dissimilarity matrix among all units compatible with the selected equivalence must be computed. Second, building on that, a partition is obtained via some classical clustering technique, usually hierarchical clustering.

In contrast with the indirect approaches, the direct approaches partition units by directly optimizing some criterion function (which again must be compatible with the selected equivalence). Direct approaches vary according to both the criterion function they optimize and the optimization method. For instance, the criterion function for binary networks could be the number of

errors in blocks or, for both binary and valued networks, the sum of squares of deviations from the block mean (analogous to Ward's criterion function or k -means criterion from classical cluster analysis).

Most deterministic approaches are only able to find partitions compatible with structural equivalence. A notable exception is Patrick Doreian, Vladimir Batagelj, and Anuška Ferligoj's generalized blockmodeling. Generalized blockmodeling is also able to find partitions compatible with regular and generalized equivalence; therefore, it can be used to find partitions and blockmodels with specific properties. When using generalized blockmodeling, some or all parts of the blockmodel can be prespecified.

BONFERRONI PROCEDURE

The Bonferroni procedure is a statistical adjustment to the significance level of hypothesis tests when multiple tests are being performed. The purpose of an adjustment such as the Bonferroni procedure is to reduce the probability of identifying significant results that do not exist, that is, to guard against making Type I errors (rejecting null hypotheses when they are true) in the testing process. This potential for error increases with an increase in the number of tests being performed in a given study and is due to the multiplication of probabilities across the multiple tests. The Bonferroni procedure is often used as an adjustment in multiple comparisons after a significant finding in an analysis of variance (ANOVA) or when constructing simultaneous confidence intervals for several population parameters, but

more broadly, it can be used in any situation that involves multiple tests. The Bonferroni procedure is one of the more commonly used procedures in multiple testing situations, primarily because it is an easy adjustment to make. A strength of the Bonferroni procedure is its ability to maintain Type I error rates at or below a nominal value. A weakness of the Bonferroni procedure is that it often overcorrects, making testing results too conservative because of a decrease in statistical power.

A variety of other procedures have been developed to control the overall Type I error level when multiple tests are performed. Some of these other multiple comparison and multiple testing procedures, including the Student–Newman–Keuls procedure, are derivatives of the Bonferroni procedure, modified to make the procedure less conservative without sacrificing Type I error control. Other multiple comparison and multiple testing procedures are simulation based and are not directly related to the Bonferroni procedure.

This entry describes the procedure's background, explains the procedure, and provides an example. This entry also presents applications for the procedure and examines recent research.

Background

The Bonferroni procedure is named after the Italian mathematician Carlo Emilio Bonferroni. Although his work was in mathematical probability, researchers have since applied his work to statistical inference. Bonferroni's principal contribution to statistical inference was the identification of the probability inequality that bears his name.

Explanation

The Bonferroni procedure is an application of the *Bonferroni inequality* to the probabilities associated with multiple testing. It prescribes using an adjustment to the significance level for individual tests when simultaneous statistical inference for several tests is being performed. The adjustment can be used for bounding simultaneous confidence intervals, as well as for simultaneous testing of hypotheses.

The Bonferroni inequality states the following:

1. Let $A_i, i = 1$ to k , represent k events. Then,

$$P\left(\bigcap_{i=1}^k A_i\right) \geq 1 - \sum_{i=1}^k P(\bar{A}_i), \text{ where } \bar{A}_i \text{ is the complement of the event } A_i.$$

2. Consider the mechanics of the Bonferroni inequality,

$$P\left(\bigcap_{i=1}^k A_i\right) \geq 1 - \sum_{i=1}^k P(\bar{A}_i),$$

Figure 1 Illustration of Bonferroni's Inequality

Note: A_1 = event 1; A_2 = event 2; $P(A_1)$ = probability of A_1 ; $P(A_2)$ = probability of A_2 . Interaction between events results in redundancy in probability.

3. and rewrite the inequality as follows:

$$1 - P\left(\bigcap_{i=1}^k A_i\right) \leq \sum_{i=1}^k P(\bar{A}_i).$$

Now, consider $\bar{A}_i$ as a Type I error in the i th test in a collection of k hypothesis tests. Then $P\left(\bigcap_{i=1}^k A_i\right)$ represents the probability that no Type I errors occur in the k hypothesis tests, and $1 - P\left(\bigcap_{i=1}^k A_i\right)$ represents the probability that at least one Type I error occurs in the k hypothesis tests. $P(\bar{A}_i)$ represents the probability of a Type I error in the i th test, and we can label this probability as $\alpha_i = P(\bar{A}_i)$. So Bonferroni's inequality implies that the probability of at least one Type I error occurring in k hypothesis tests is $\leq \sum_{i=1}^k \alpha_i$.

If, as is often assumed, all k tests have the same probability of a Type I error, α , then we can conclude that the probability of at least one Type I error occurring in k hypothesis tests is $\leq k\alpha$.

Consider an illustration of Bonferroni's inequality in the simple case in which $k = 2$: Let the two events A_1 and A_2 have probabilities $P(A_1)$ and $P(A_2)$, respectively. The sum of the probabilities of the two events is clearly greater than the probability of the union of the two events because the former counts the probability of the intersection of the two events twice, as shown in Figure 1.

The Bonferroni procedure is simple in the sense that a researcher need only know the number of tests to be performed and the probability of a Type I error for those tests in order to construct this upper bound on the experiment-wise error rate. However, as mentioned earlier, the Bonferroni procedure is often criticized for being too conservative. Consider that the researcher

does not typically know what the actual Type I error rate is for a given test. Rather, the researcher constructs the test so that the maximum allowable Type I error rate is α . Then the actual Type I error rate may be considerably less than α for any given test.

For example, suppose a test is constructed with a nominal $\alpha = .05$. Suppose the researcher conducts $k = 10$ such tests on a given set of data, and the actual Type I error rate for each of the tests is .04. Using the Bonferroni procedure, the researcher concludes that the experiment-wise error rate is at most $10 \times .05$, or .50. The error rate in this scenario is in fact .40, which is considerably less than .50.

As another example, consider the extreme case in which all $k = 10$ hypothesis tests are exactly dependent on each other—the same test is conducted 10 times on the same data. In this scenario, the experiment-wise error rate does not increase because of the multiple tests. In fact, if the Type I error rate for one of the tests is $\alpha = .05$, the experiment-wise error rate is the same, .05, for all 10 tests simultaneously. We can see this result

from the Bonferroni inequality: $P\left(\bigcap_{i=1}^k A_i\right) = P(A_i)$ when the events, A_i , are all the same because $\bigcap_{i=1}^k A_i = A_i$. The

Bonferroni procedure would suggest an upper bound on this experiment-wise probability as .50—overly conservative by 10-fold! It would be unusual for a researcher to conduct k equivalent tests on the same data. However, it would not be unusual for a researcher to conduct k tests and for many of those tests, if not all, to be partially interdependent. The more interdependent the tests are, the smaller the experiment-wise error rate and the more overly conservative the Bonferroni procedure is.

Other procedures have sought to correct for inflation in experiment-wise error rates without being as conservative as the Bonferroni procedure. However, none are as simple to use. These other procedures include the Student–Newman–Keuls, Tukey, and Scheffé procedures, to name a few. Descriptions of these other procedures and their uses can be found in many basic statistical methods textbooks, as well as this encyclopedia.

Example

Consider the case of a researcher studying the effect of three different teaching methods on the average words per minute (μ_1, μ_2, μ_3) at which a student can read. The researcher tests three hypotheses: $\mu_1 = \mu_2$ (vs. $\mu_1 \neq \mu_2$), $\mu_1 = \mu_3$ (vs. $\mu_1 \neq \mu_3$), and $\mu_2 = \mu_3$ (vs. $\mu_2 \neq \mu_3$). Each test is conducted at a nominal level, $\alpha_0 = .05$, resulting in a comparison-wise error rate of $\alpha_c = .05$ for

each test. Denote A_1 , A_2 , and A_3 as the event of falsely rejecting the null hypotheses 1, 2, and 3, respectively, and denote p_1 , p_2 , and p_3 the probability of events A_1 , A_2 , and A_3 , respectively. These would be the individual p values for these tests. It may be assumed that some dependence exists among the three events, A_1 , A_2 , and A_3 , principally because the events are all based on data collected from a single study. Consequently, the experiment-wise error rate, the probability of falsely rejecting any of the three null hypotheses, is at least equal to $\alpha_e = .05$ but potentially as large as $.05 \times 3 = .15$. For this reason, we may apply the Bonferroni procedure by dividing our nominal level of $\alpha_0 = .05$ by $k = 3$ to obtain $\alpha_0^* = .0167$. Then, rather than comparing the p values p_1 , p_2 , and p_3 to $\alpha_0 = .05$, we compare them to $\alpha_0^* = .0167$. The experiment-wise error rate is therefore adjusted down so that it is less than or equal to the original intended nominal level of $\alpha_0 = .05$.

It should be noted that although the Bonferroni procedure is often used in the comparison of multiple means, because the adjustment is made to the nominal level, α_0 , or to the test's resulting p value, the multiple tests could be hypothesis tests of any population parameters based on any probability distributions. So, for example, one experiment could involve a hypothesis test regarding a mean and another hypothesis test regarding a variance, and an adjustment based on $k = 2$ could be made to the two tests to maintain the experiment-wise error rate at the nominal level.

Applications

As noted above, the Bonferroni procedure is used primarily to control the overall α level (i.e., the experiment-wise level) when multiple tests are being performed. Many statistical procedures have been developed at least partially for this purpose; however, most of those procedures have applications exclusively in the context of making multiple comparisons of group means after finding a significant ANOVA result. While the Bonferroni procedure can also be used in this context, one of its advantages over other such procedures is that it can also be used in other multiple testing situations that do not initially entail an omnibus test such as ANOVA.

For example, although most statistical tests do not advocate using a Bonferroni adjustment when testing beta coefficients in a multiple regression analysis, it has been shown that the overall Type I error rate in such an analysis involving as few as eight regression coefficients can exceed .30, resulting in almost a 1 in 3 chance of falsely rejecting a null hypothesis. Using a Bonferroni adjustment when one is conducting these tests would control that overall Type I error rate. Similar adjustments can be used to test for main

effects and interactions in ANOVA and multivariate ANOVA designs because all that is required to make the adjustment is that the researcher knows the number of tests being performed. The Bonferroni adjustment has been used to adjust the experiment-wise Type I error rate for multiple tests in a variety of disciplines, such as medical, educational, and psychological research, to name a few.

Recent Research

One of the main criticisms of the Bonferroni procedure is the fact that it overcorrects the overall Type I error rate, which results in lower statistical power. Many modifications to this procedure have been proposed over the years to try to alleviate this problem. Most of these proposed alternatives can be classified either as *step-down procedures* (e.g., the Holm method), which test the most significant (and, therefore, smallest) p value first, or *step-up procedures* (e.g., the Hochberg method), which begin testing with the least significant (and largest) p value. With each of these procedures, although the tests are all being conducted concurrently, each hypothesis is not tested at the same time or at the same level of significance.

More recent research has attempted to find a divisor between 1 and k that would protect the overall Type I error rate at or below the nominal .05 level but closer to that nominal level so as to have a lesser effect on the power to detect actual differences. This attempt was based on the premise that making no adjustment to the α level is too liberal an approach (inflating the experiment-wise error rate), and dividing by the number of tests, k , is too conservative (overadjusting that error rate). It was shown that the optimal divisor is directly determined by the proportion of nonsignificant differences or relationships in the multiple tests being performed. Based on this result, a divisor of $k(1 - q)$, where q = the proportion of nonsignificant tests, did the best job of protecting against Type I errors without sacrificing as much power. Unfortunately, researchers often do not know, a priori, the number of nonsignificant tests that will occur in the collection of tests being performed. Consequently, research has also shown that a practical choice of the divisor is $k/1.5$ (rounded to the nearest integer) when the number of tests is greater than three. This modified Bonferroni adjustment will outperform alternatives in keeping the experiment-wise error rate at or below the nominal .05 level and will have higher power than other commonly used adjustments.

BOOTSTRAPPING

Bootstrapping is a computerized simulation operation that involves random resampling from the data set one is using to produce perhaps thousands of new data sets that have similar participant compositions to the original data set. For example, if a researcher had a data set containing 500 participants, the bootstrapping procedure would sample from the original data set to create new data sets, each of 500 participants. It is used to determine the statistical significance of parameter estimates whose significance cannot be tested using established statistical distributions (e.g., *t*, *F*, and chi-square distributions). One might use bootstrapping when data are nonnormal or the distribution of a parameter is difficult to anticipate (e.g., indirect effects in path analysis). Bootstrapping estimates the standard error (standard deviation of a set

of statistical values such as a set of means from multiple samples) for a given statistical analysis, as well as confidence intervals for a parameter. Standard errors and confidence intervals are key to determining statistical significance.

This entry describes how and why bootstrapping samples are created, and how bootstrap samples indicate statistical significance of results. Other resampling techniques that are alternatives to bootstrapping are also introduced. The entry concludes with a review of software that can be used for bootstrapping.

How Bootstrap Samples Are Drawn

The key to bootstrapping is that the new bootstrap simulation samples are drawn *with replacement*. Imagine that a researcher places five ping-pong balls into a hat, the number “1” having been painted onto one ball, a “2” onto another, and the same for “3,” “4,” and “5.” Suppose further that the researcher plans to draw a random sample of three balls. The term *with replacement* refers to the fact that the ball that is drawn first is put back into the hat to possibly be drawn again. The same is done with the ball drawn second. Hence, the final three-ball sample conceivably could consist of balls 2, 2, and 4, or balls 1, 3, and 3, for example. If sampling is done *without* replacement, a ball selected into the sample is not returned to the hat; hence, the same number cannot appear more than once in the sample. Possible samples might, therefore, include balls 1, 2, and 3, or balls 2, 4, and 5.

Without replacement, drawing 500 people to create new data sets of 500 (a more realistic example for bootstrapping) would simply keep reproducing the original sample of the same 500 people. With replacement, however, the same participant in the original data set could be selected into a new sample, put back into the original sampling pool, then selected again into the same new sample. Other participants in the original sample may not be selected at all into one of the new samples. Suppose a researcher who has a sample of 500 participants wishes to draw 1,000 new bootstrap samples, each with the same sample size of 500. One of these bootstrap samples might include participants with the identification (ID) number 1, ID number 2, ID number 2 again (so that his or her data are used twice), ID number 5, ID number 6, and so forth, all the way to a total of 500 participants. Another bootstrap sample might include participants with ID number 3, ID number 3 again, ID number 4, ID number 7, ID number 7 again, ID number 7 a third time, ID number 10, and so forth.

The Rationale for Bootstrap Samples

Amassing perhaps 1,000 or 5,000 synthetic samples from an original source sample is thought to approximate the real samples that would appear if a researcher drew thousands of random samples from a population of actual people (e.g., residents of Chicago or London). Bootstrapping is used in place of actual population sampling because it would be virtually impossible logistically and financially to draw and interview people comprising thousands of random samples of conventional sizes (e.g., 500–1,000 respondents) from a given geographic entity. For this reason, the unseen source of the bootstrap samples is sometimes referred to as a *surrogate population*, with the resulting samples sometimes called *phantom samples*.

How Bootstrap Samples Indicate Statistical Significance of a Result

Once the bootstrap samples are obtained, the computer program runs the desired analysis (e.g., multiple regression) in each sample and compiles a histogram of the focal statistic (e.g., a beta coefficient from one predictor to the outcome) in each of the bootstrap samples. This step, thus, creates a sampling distribution of the beta coefficient. As a consequence of the Central Limit Theorem, the histogram of regression coefficients will tend toward a normal distribution. Christoph Hanck and colleagues (2020) provide an interactive online animated demonstration of the process. Statistics blogger Jim Frost (2020) notes that the bootstrap method can analyze a large variety of sample statistics, including the mean, median, mode, standard deviation, analysis of variance, correlations, regression coefficients, proportions, odds ratios, variance in binary data, and multivariate statistics.

One way to obtain a bootstrap confidence interval (95% CI, in this example) is to remove the highest 2.5% and lowest 2.5% of parameter estimates (here, regression coefficients) from the histogram of results from the bootstrap samples. This is known as a *percentile confidence interval* and is not necessarily symmetric to the left and right of the mean of the focal parameter. The percentile CI is considered a nonparametric technique. After removal of the upper and lower 2.5% of the distribution, the remaining range from the lowest to highest parameter estimate constitutes the CI. With a large sample and a roughly normal bootstrap sampling distribution, a CI can be determined via equations involving the bootstrap standard error. The focal parameter (e.g., regression coefficient) is significantly different from zero if the CI end points are either both

greater than zero (i.e., significantly positive coefficient) or both less than zero (i.e., significantly negative coefficient). Software packages typically display the lower and upper end points of confidence intervals in their output.

Refinements to Bootstrap Solutions

More complex alternatives, including bias-corrected and accelerated (BCa) CIs, can be used to adjust percentile intervals to make them more accurate. Two flaws for which the BCa attempts to correct are *bias* and *skewness* in the distribution. According to David Moore and colleagues (2016, pp. 16–10), “Bias is the difference between the mean of the resample means and the original [sample] mean.” Skewness is used here in the ordinary sense, in terms of asymmetry between the two sides of the distribution. Moore and colleagues note that calculation of such CIs is highly technical but urge the use of BCa or similar methods when available in the software package one is using.

Illustration With Path Analysis Indirect Effects

One common use of bootstrapping in psychology and other social sciences is to determine the significance of indirect or mediational effects in path analysis modeling from an antecedent variable to an outcome variable. The magnitude of indirect effects is calculated by multiplying the two respective path coefficients, from an antecedent to a proposed mediator variable and from the mediator to an outcome (e.g., exposure to stressful life circumstances leading to increases in cortisol and cortisol leading to physical symptoms). Bootstrap tests of the significance of indirect effects would be implemented in line with the aforementioned general steps, by generating large numbers of random resamplings of the original data set, running path analysis models in each of the new synthetic samples, and plotting a histogram of the resulting indirect effects. Andrew Hayes has created a macro (add-on) to perform bootstrap mediation (and other) analyses with indirect effects in the SPSS and SAS packages (with an R macro in development at this writing).

Alternative Resampling Techniques

To provide context on bootstrapping’s capabilities, limitations, and scope, two alternatives to it that also use resampling to determine statistical significance—jackknifing and permutation tests—are discussed briefly. Jackknifing creates repeated synthetic samples by deleting one observation from the original sample.

Permutation tests provide a way to assess significance by comparing a test statistic from one's sample with a critical value (akin to how, before computers automatically generated p levels for t - or chi-square tests, researchers used to consult tables in the back of a statistics textbook to see if their obtained statistic exceeded a critical value for significance). Permutation tests create synthetic distributions (centered at zero, akin to a z -distribution, representing the null hypothesis) from one's data, providing a way to compare an obtained test statistic to a critical value.

Bootstrapping Versus Other Resampling Techniques

Because bootstrapping and jackknifing are the most similar to each other and often are discussed in conjunction with each other, direct comparison of the two techniques is warranted. First, jackknifing is a simpler approximation to bootstrapping, suggesting the latter should be preferred unless prohibitively difficult (e.g., limited computer resources). Second, properties of a statistical parameter including *linearity* (i.e., a function involving only basic mathematical operations such as adding and multiplying, as opposed to raising numbers to higher powers such as squaring) and *smoothness* affect the usefulness of bootstrapping and jackknifing. Jackknife analyses of nonsmooth parameters such as the median and of nonlinear functions perform poorly, suggesting that bootstrapping can be used with a broader range of statistics than can jackknifing. Third, as discussed by Rodgers, the sampling frame of possible combinations of cases is much larger for bootstrapping than for other resampling techniques, making bootstrapping advantageous. On the other hand, bootstrapping is prone to difficulties with small samples.

Software Packages for Bootstrapping

The major statistical packages have general bootstrapping routines (i.e., applicable to a wide variety of techniques), sometimes at extra cost beyond the basic package. SAS provides macros known as %BOOT for a normally distributed sampling distribution and %BOOTCI for confidence intervals from nonnormal distributions. SPSS provides bootstrap options in its menu-driven modules for several techniques (e.g., mean, correlation). Stata offers syntax-based bootstrap routines. Finally, many different bootstrap routines in R can easily be found through internet searches.

BOX-AND-WHISKER PLOT

A box-and-whisker plot, or box plot, is a tool used to visually display the range, distribution symmetry, and central tendency of a distribution in order to illustrate

the variability and the concentration of values within a distribution. The box plot is a graphical representation of the five-number summary, or a quick way of summarizing the center and dispersion of data for a variable. The five-number summary includes the minimum value, 1st (lower) quartile (Q_1), median, 3rd (upper) quartile (Q_3), and the maximum value. Outliers are also indicated on a box plot. Box plots are especially useful in research methodology and data analysis as one of the many ways to visually represent data. From this visual representation, researchers glean several pieces of information that may aid in drawing conclusions, exploring unexpected patterns in the data, or prompting the researcher to develop future research questions and hypotheses. This entry provides an overview of the history of the box plot, key components and construction of the box plot, and a discussion of the appropriate uses of a box plot.

History

A box plot is one example of a graphical technique used within exploratory data analysis (EDA). EDA is a statistical method used to explore and understand data from several angles in social science research. EDA grew out of work by John Tukey and his associates in the 1960s and was developed to broadly understand the data, graphically represent data, generate hypotheses and build models to guide research, add robust measures to an analysis, and aid the researcher in finding the most appropriate method for analysis. EDA is especially helpful when the researcher is interested in identifying any unexpected or misleading patterns in the data. Although there are many forms of EDA, researchers must employ the most appropriate form given the specific procedure's purpose and use.

Definition and Construction

One of the first steps in any statistical analysis is to describe the central tendency and the variability of the values for each variable included in the analysis. The researcher seeks to understand the center of the distribution of values for a given variable (*central tendency*) and how the rest of the values fall in relation to the center (*variability*). Box plots are used to visually display variable distributions through the display of robust statistics, or statistics that are more resistant to the presence of outliers in the data set. Although there are somewhat different ways to construct box plots depending on the way in which the researcher wants to display outliers, a box plot always provides a visual display of the five-number summary. The median is

defined as the value that falls in the middle after the values for the selected variable are ordered from lowest to highest value, and it is represented as a line in the middle of the rectangle within a box plot. As it is the central value, 50% of the data lie above the median and 50% lie below the median. When the distribution contains an odd number of values, the median represents an actual value in the distribution. When the distribution contains an even number of values, the median represents an average of the two middle values.

To create the rectangle (or box) associated with a box plot, one must determine the 1st and 3rd quartiles, which represent values (along with the median) that divide all the values into four sections, each including approximately 25% of the values. The 1st (lower) quartile (Q_1) represents a value that divides the lower 50% of the values (those below the median) into two equal sections, and the 3rd (upper) quartile (Q_3) represents a value that divides the upper 50% of the values (those above the median) into two equal sections. As with calculating the median, quartiles may represent the average of two values when the number of values below and above the median is even. The rectangle of a box plot is drawn such that it extends from the 1st quartile through the 3rd quartile and thereby represents the *interquartile range* (IQR; the distance between the 1st and 3rd quartiles). The rectangle includes the median.

In order to draw the “whiskers” (i.e., lines extending from the box), one must identify *fences*, or values that represent minimum and maximum values that would not be considered outliers. Typically, fences are calculated to be $Q - 1.5 \text{ IQR}$ (lower fence) and $Q_3 + 1.5 \text{ IQR}$ (upper fence). Whiskers are lines drawn by connecting the most extreme values that fall within the fence to the lines representing Q_1 and Q_3 . Any value that is greater than the upper fence or lower than the lower fence is considered an outlier and is displayed as a special symbol beyond the whiskers. Outliers that extend beyond the fences are typically considered *mild outliers* on the box plot. An *extreme outlier* (i.e., one that is located beyond 3 times the length of the IQR from the 1st quartile (if a low outlier) or 3rd quartile (if a high outlier)) may be indicated by a different symbol. Figure 1 provides an illustration of a box plot.

Box plots can be created in either a vertical or a horizontal direction. (In this entry, a vertical box plot is generally assumed for consistency.) They can often be very helpful when one is attempting to compare the distributions of two or more data sets or variables on the same scale, in which case they can be constructed side by side to facilitate comparison.

Figure 1 Box Plot Created With a Data Set and SPSS (an IBM company, formerly called PASW® Statistics)

Note: Data set values: 2.0, 2.0, 2.0, 3.0, 3.0, 5.0, 6.0, 6.0, 7.0, 7.0, 8.0, 8.0, 9.0, 10.0, 22.0. Defining features of this box plot: median = 6.0; first (lower) quartile = 3.0; third (upper) quartile = 8.0; interquartile range (IQR) = 5.0; lower inner fence = 4.5; upper inner fence = 15.5; range = 20.0; mild outlier = 22.0.

Steps to Creating a Box Plot

The following six steps are used to create a vertical box plot:

1. Order the values within the data set from smallest to largest and calculate the median, lower quartile (Q_1), upper quartile (Q_3), and minimum and maximum values.
2. Calculate the IQR.
3. Determine the lower and upper fences.
4. Using a number line or graph, draw a box to mark the location of the 1st and 3rd quartiles. Draw a line across the box to mark the median.
5. Make a short horizontal line below and above the box to locate the minimum and maximum values that fall within the lower and upper fences. Draw a line connecting each short horizontal line to the box. These are the box plot whiskers.
6. Mark each outlier with an asterisk or an "o."

Making Inferences

R. Lyman Ott and Michael Longnecker described five inferences that one can make from a box plot. First, the researcher can easily identify the median of the data by locating the line drawn in the middle of the box. Second, the researcher can easily identify the variability of the data by looking at the length of the box. Longer boxes illustrate greater variability whereas shorter box lengths illustrate a tighter distribution of the data around the median. Third, the researcher can easily examine the symmetry of the middle 50% of the data distribution by looking at where the median line falls in the box. If the median is in the middle of the box, then the data are evenly distributed on either side of the median, and the distribution can be considered symmetrical. Fourth, the researcher can easily identify outliers in the data by the asterisks outside the whiskers. Fifth, the researcher can easily identify the skewness of the distribution. On a distribution curve, data skewed to the right show more of the data to the left with a long “tail” trailing to the right. The opposite is shown when the data are skewed to the left. To identify skewness on a box plot, the researcher looks at the length of each half of the box plot. If the lower or left half of the box plot appears longer than the upper or right half, then the data are skewed in the lower direction or skewed to the left. If the upper half of the box plot appears longer than the lower half, then the data are skewed in the upper direction or skewed to the right. If a researcher suspects the data are skewed, it is recommended that the researcher investigate further by means of a histogram.

Variations

Over the past few decades, the availability of several statistical software packages has made EDA easier for social science researchers. However, these statistical packages may not calculate parts of a box plot in the same way, and hence some caution is warranted in their use. One study conducted by Michael Frigge, David C. Hoaglin, and Boris Iglewicz found that statistical packages calculate aspects of the box plot in different ways. In one example, the authors used three different statistical packages to create a box plot with the same distribution. Though the median looked approximately the same across the three box plots, the differences appeared in the length of the whiskers. The reason for the differences was the way the statistical packages used the interquartile range to calculate the whiskers. In general, to calculate the whiskers, one multiplies the interquartile range by a constant and then adds the result to Q_3 and subtracts it from Q_1 . Each package used a different constant, ranging from 1.0 to 3.0. Though packages

typically allow the user to adjust the constant, a package typically sets a default, which may not be the same as another package's default. This issue, identified by Frigge and colleagues, is important to consider because it guides the identification of outliers in the data. In addition, such variations in calculation lead to the lack of a standardized process and possibly to consumer confusion. Therefore, the authors provided three suggestions to guide the researcher in using statistical packages to create box plots. First, they suggested using a constant of 1.5 when the number of observations is between 5 and 20. Second, they suggested using a constant of 2.0 for outlier detection and rejection. Finally, they suggested using a constant of 3.0 for extreme cases. In the absence of standardization across statistical packages, researchers should understand how a package calculates whiskers and follow the suggested constant values.

Applications

As with all forms of data analysis, there are many advantages and disadvantages, appropriate uses, and certain precautions researchers should consider when using a box plot to display distributions. Box plots provide a good visualization of the range and potential skewness of the data. A box plot may provide the first step in exploring unexpected patterns in the distribution because box plots provide a good indication of how the data are distributed around the median. Box plots also clearly mark the location of mild and extreme outliers in the distribution. Other forms of graphical representation that graph individual values, such as dot plots, may not make this clear distinction. When used appropriately, box plots are useful in comparing more than one sample distribution side by side. In other forms of data analysis, a researcher may choose to compare data sets using a t test to compare means or an F test to compare variances. However, these methods are more vulnerable to skewness in the presence of extreme values. These methods must also meet normality and equal variance assumptions. Alternatively, box plots can compare the differences between variable distributions without the need to meet certain statistical assumptions.

However, unlike other forms of EDA, box plots show less detail than a researcher may need. For one, box plots may display only the five-number summary. They do not provide frequency measures or the quantitative measure of variance and standard deviation. Second, box plots are not used in a way that allows the researcher to compare the data with a normal distribution, which stem plots and histograms do allow. Finally, box plots would not be appropriate to use with a small

sample size because of the difficulty in detecting outliers and finding patterns in the distribution.

Besides taking into account the advantages and disadvantages of using a box plot, one should consider a few precautions. In a 1990 study conducted by John T. Behrens and colleagues, participants frequently made judgment errors in determining the length of the box or whiskers of a box plot. In part of the study, participants were asked to judge the length of the box by using the whisker as a judgment standard. When the whisker length was longer than the box length, the participants tended to overestimate the length of the box. When the whisker length was shorter than the box length, the participants tended to underestimate the length of the box. The same result was found when the participants judged the length of the whisker by using the box length as a judgment standard. The study also found that compared with vertical box plots, box plots positioned horizontally were associated with fewer judgment errors.

C PARAMETER

See Guessing Parameter

CANONICAL CORRELATION ANALYSIS

Canonical correlation analysis (CCA) is a multivariate statistical method that analyzes the relationship between two *sets* of variables, in which each set contains at least two variables. It is the most general type of the general linear model, with multiple regression, multiple analysis of variance, analysis of variance, and discriminant function analysis all being special cases of CCA.

Although the method has been available for more than 70 years, its use has been somewhat limited until fairly recently due to its lack of inclusion in common statistical programs and its rather labor-intensive calculations. Currently, however, many computer programs do include CCA, and thus the method has become somewhat more widely used.

This entry begins by explaining the basic logic of and defining important terms associated with CCA. Next, this entry discusses the interpretation of CCA results, statistical assumptions, and limitations of CCA. Last, it provides an example from the literature.

Basic Logic

The logic of CCA is fairly straightforward and can be explained best by likening it to a “multiple-multiple regression.” That is, in multiple regression a researcher is interested in discovering the variables (among a set

of variables) that best predict a single variable. The set of variables may be termed the *independent*, or *predictor*, *variables*; the single variable may be considered the *dependent*, or *criterion*, *variable*. CCA is similar, except that there are multiple dependent variables, as well as multiple independent variables. The goal is to discover the pattern of variables (on both sides of the equation) that combine to produce the highest predictive values for both sets. The resulting combination of variables for each side, then, may be thought of as a kind of latent or underlying variable that describes the relation between the two sets of variables.

A simple example from the literature illustrates its use: A researcher is interested in investigating the relationships among gender, social dominance orientation, right wing authoritarianism, and three forms of prejudice (stereotyping, opposition to equality, and negative affect). Gender, social dominance orientation, and right wing authoritarianism constitute the predictor set; the three forms of prejudice are the criterion set. Rather than computing three separate multiple regression analyses (*viz.*, the three predictor variables regressing onto one criterion variable, one at a time), the researcher instead computes a CCA on the two sets of variables to discern the most important predictor(s) of the three forms of prejudice. In this example, the CCA revealed that social dominance orientation emerged as the overall most important dimension that underlies all three forms of prejudice.

Important Terms

To appreciate the various terms associated with CCA, it is necessary to have a basic understanding of the analytic procedure itself. The first step in CCA involves collapsing each person’s score for each variable, in the two variable sets, into a single composite, or “synthetic,” variable. These synthetic variables are created such that the

correlation between the two sets is maximal. This occurs by weighting each person's score and then summing the weighted scores for the respective variable sets. Pairs of linear synthetic variables created by this maximization process are called *canonical variates*. The bivariate correlation between the pairs of variates is the *canonical correlation* (sometimes called the *canonical function*). There will be two canonical variates produced for each canonical correlation, with one variate representing the predictor variables and the other representing the criterion variables. The total number of canonical variate pairs produced is equal to the number of variables in either the criterion or predictor set, whichever is smaller. Finally, squaring the canonical correlation coefficient yields the proportion of variance the pairs of canonical variates (not the original variables) linearly share.

Interpretation of Results

Similar to other statistical methods, the first step in CCA is determining the statistical significance of the canonical correlation coefficients associated with the variates. Different tests of significance (e.g., Wilks's lambda, Bartlett's test) are generally reported in statistical computer programs, and only those canonical correlations that differ significantly from zero are subsequently interpreted. With respect to the previously mentioned example (social dominance and right wing authoritarianism), three canonical variates were produced (because the smallest variable set contained three variables), but in that case, only the first two were significant. Canonical correlations are reported in descending order of importance, and normally only the first one or two variates are significant. Further, even if a canonical correlation is significant, most researchers do not interpret those below .30 because the amount of variance shared (that is, the correlation squared) is so small that the canonical variate is of little practical significance.

A second method of interpretation involves evaluating the degree to which the individual variables load onto their respective canonical variates. Variables that have high loadings on a particular variate essentially have more in common with it and thus should be given more weight in interpreting its meaning. This is directly analogous to factor loading in factor analysis and indicates the degree of importance of the individual variables in the overall relation between the criterion and predictor variable sets. The commonly accepted convention is to interpret only those variables that achieve loadings of .40 or higher. The term *structure coefficient* (or *canonical factor loadings*) refers to the correlation between each variable and its respective canonical variate, and its interpretation is similar to the bivariate correlation coefficient. In addition, as with correlation

coefficient interpretation, both the direction and the magnitude of the structure coefficient are taken into consideration. The structure coefficient squared represents the amount of variance a given variable accounts for in its own canonical variate, based on the set of variables to which it belongs. Structure coefficients, then, represent the extent to which the individual variables and their respective canonical variates are related, and in effect, their interpretation forms the crux of CCA.

Statistical Assumptions

Reliable use of CCA requires multivariate normality, and the analysis itself proceeds on the assumption that all variables and linear combinations of variables approximate the normal distribution. However, with large sample sizes, CCA can be robust to this violation.

The technique also requires minimal measurement error (e.g., alpha coefficients of .80 or above) because low scale reliabilities attenuate correlation coefficients, which, ultimately, reduces the probability of detecting a significant canonical correlation. In addition, it is very useful to have an adequate range of scores for each variable because correlation coefficients can also be attenuated by truncated or restricted variance; thus, as with other correlation methods, sampling methods that increase score variability are highly recommended. Outliers (that is, data points that are well "outside" a particular distribution of scores) can also significantly attenuate correlation, and their occurrence should be minimized or, if possible, eliminated.

For conventional CCA, linear relationships among variables are required, although CCA algorithms for nonlinear relationships are currently available. And, as with other correlation-based analyses, low multicollinearity among variables is assumed. Multicollinearity occurs when variables in a correlation matrix are highly correlated with each other, a condition that reflects too much redundancy among the variables. As with measurement error, high multicollinearity also reduces the magnitudes of correlation coefficients.

Stable (i.e., reliable) canonical correlations are more likely to be obtained if the sample size is large. It is generally recommended that adequate samples should range from 10 to 20 cases per variable. So, for example, if there are 10 variables, one should strive for a minimum of 100 cases (or participants). In general, the smaller the sample size, the more unstable the CCA.

Limitation

The main limitation associated with CCA is that it is often difficult to interpret the meaning of the resulting canonical variates. As others have noted, a mathematical

procedure that maximizes correlations may not necessarily yield a solution that is maximally interpretable. This is a serious limitation and may be the most important reason CCA is not used more often. Moreover, given that it is a descriptive technique, the problems with interpreting the meaning of the canonical correlation and associated variates are particularly troublesome. For example, suppose a medical sociologist found that low unemployment level, high educational level, and high crime rate (the predictor variables) are associated with good medical outcomes, low medical compliance, and high medical expenses (the criterion variables). What might this pattern mean? Perhaps people who are employed, educated, and live in high crime areas have expensive, but good, health care, although they do not comply with doctors however, compared with other multivariate techniques, with CCA there appears to be greater difficulty in extracting the meaning (i.e., the latent variable) from the obtained results.

Example in the Literature

In the following example, drawn from the adolescent psychopathology literature, a CCA was performed on two sets of variables, one (the predictor set) consisting of personality pattern scales of the Millon Adolescent Clinical Inventory, the other (the criterion set) consisting of various mental disorder scales from the Adolescent Psychopathology Scale. The goal of the study was to discover whether the two sets of variables were significantly related (i.e., would there exist a multivariate relationship?), and if so, how might these two sets be related (i.e., how might certain personality styles be related to certain types of mental disorders?).

The first step in interpretation of a CCA is to present the significant variates. In the above example, four significant canonical variates emerged; however, only the first two substantially contributed to the total amount of variance (together accounting for 86% of the total variance), and thus only those two were interpreted. Second, the structure coefficients (canonical loadings) for the two significant variates were described. Structure coefficients are presented in order of absolute magnitude and are always interpreted as a pair. By convention, only coefficients greater than .40 are interpreted. In this case, for the first canonical variate, the predictor set accounted for 48% (R^2) of the variance in the criterion set. Further examination of the canonical loadings for this variate showed that the predictor set was represented mostly by the Conformity subscale (factor loading of .92) and was related to lower levels of mental disorder symptoms. The structure coefficients for the second canonical variate were then interpreted in a similar manner.

The last, and often most difficult, step in CCA is to interpret the overall meaning of the analysis. Somewhat similar to factor analysis interpretation, latent variables are inferred from the pattern of the structure coefficients for the variates. A possible interpretation of the above example might be that an outgoing conformist personality style is predictive of overall better mental health for adolescents at risk for psychopathology.

A Flexible Tool

The purpose of canonical correlation analysis, a multivariate statistical technique, is to analyze the relationships between two sets of variables, in which each set contains at least two variables. It is appropriate for use when researchers want to know whether the two sets are related and, if so, how they are related. CCA produces canonical variates based on linear combinations of measured variables. The variates are a kind of latent variable that relates one set of variables to the other set. CCA shares many of the statistical assumptions of other correlational techniques. The major limitation of CCA lies in its interpretability; that is, although significant variates can be derived mathematically, they may not necessarily be meaningful.

CASE STUDY

Case study research is a versatile approach to research in social and behavioral sciences. Case studies consist of detailed inquiry into a bounded entity or unit (or entities) in which the researcher either examines a relevant issue or reveals phenomena through the process of examining the entity within its social and cultural context. Case study has gained in popularity in recent

years. However, it is difficult to define because researchers view it alternatively as a research design, an approach, a method, or even an outcome. This entry examines case study through different lenses to uncover the versatility in this type of research approach.

Overview

Case study researchers have conducted studies in traditional disciplines such as anthropology, economics, history, political science, psychology, and sociology. Case studies have also emerged in areas such as medicine, law, nursing, business, administration, public policy, social work, and education. Case studies may be used as part of a larger study or as a stand-alone design. Case study research may be considered a method for inquiry or an evaluation of a bounded entity, program, or system. Case studies may consist of more than one entity (unit, thing) or of several cases within one entity, but care must be taken to limit the number of cases in order to allow for in-depth analysis and description of each case.

Researchers who have written about case study research have addressed it in different ways, depending on their perspectives and points of view. Some researchers regard case study as a research process used to investigate a phenomenon in its real-world setting. Some have considered case study to be a design—a particular logic for setting up the study. Others think of case study as a qualitative approach to research that includes particular qualitative methods. Others have depicted it in terms of the final product, a written holistic examination, interpretation, and analysis of one or more entities or social units. Case study also has been defined in terms of the unit of study itself, or the entity being studied. Still other researchers consider that case study research encompasses all these notions taken together in relation to the research questions.

Case Study as a Bounded System

Although scholars in various fields and disciplines have given case study research many forms, what these various definitions and perspectives have in common is the notion from Louis Smith that case study is inquiry about a *bounded* system. Case studies may be conducted about such entities as a single person or several persons, a single classroom or classrooms, a school, a program within a school, a business, an administrator, or a specific policy, and so on. The case study also may be about a complex, integrated system, as long as researchers are able to put boundaries or limits around the system being researched.

The notion of boundedness may be understood in more than one way. An entity is naturally bounded if

the participants have come together by their own means for their own purposes having nothing to do with the research. An example would be a group of students in a particular classroom, a social club that meets on a regular basis, or the staff members in a department of a local business. The entity is naturally bounded because it consists of participants who are together for their own common purposes. A researcher is able to study the entity in its entirety for a time frame consistent with the research questions.

In other instances, an entity may be artificially bounded through the criteria set by a researcher. In this instance, the boundary is suggested by selecting from among participants to study an issue particular to some, but not all, the participants. For example, the researcher might study an issue that pertains only to a particular group of students, such as the study habits of sixth-grade students who are reading above grade level. In this situation, the case is artificially bounded because the researcher establishes the criteria for selection of the participants of the study as it relates to the issue being studied and the research questions being asked.

Selecting case study as a research design is appropriate for particular kinds of questions being asked. For example, if a researcher wants to know how a program works or why a program has been carried out in a particular way, case study can be of benefit. In other words, when a study is of an exploratory or explanatory nature, case study is well suited. In addition, case study works well for understanding processes because the researcher is able to get close to the participants within their local contexts. Case study design helps the researcher understand the complexity of a program or a policy, as well as its implementation and effects on the participants.

Design Decisions

When a researcher begins case study research, a series of decisions must be made concerning the rationale, the design, the purpose, and the type of case study. In terms of the rationale for conducting the study, Robert Stake indicated three specific forms. Case study researchers may choose to learn about a case because of their inherent interest in the case itself. A teacher who is interested in following the work of a student who presents particular learning behaviors would conduct an *intrinsic* case study. In other words, the case is self-selected due to the inquirer's interest in the particular entity. Another example could be an evaluation researcher who may conduct an intrinsic case to evaluate a particular program. The program itself is of interest, and the evaluator is not attempting to compare that program to others.

On the other hand, an *instrumental* case is one that lends itself to the understanding of an issue or phenomenon beyond the case itself. For example, examining the change in teacher practices due to an educational reform may lead a researcher to select one teacher's classroom as a case, but with the intent of gaining a general understanding of the reform's effects on classrooms. In this instance, the case selection is made for further understanding of a larger issue that may be instrumental in informing policy. For this purpose, one case may not be enough to fully understand the reform issue. The researcher may decide to have more than one case in order to see how the reform plays out in different classroom settings or in more than one school. If the intent is to study the reform in more than one setting, then the researcher would conduct a *collective* case study. Once the researcher has made a decision whether to understand the inherent nature of one case (intrinsic) or to understand a broader issue that may be represented by one or more cases (instrumental or collective), the researcher needs to decide the type of case that will illuminate the entity or issue in question.

Single-Case Design

In terms of design, a researcher needs to decide whether to examine a single case, multiple cases, or several cases embedded within a larger system. In his work with case study research, Robert Yin suggests that one way to think about conducting a study of a single case is to consider it as a holistic examination of an entity that may demonstrate the tenets of a theory (i.e., *critical case*). If the case is highly unusual and warrants in-depth explanation, it would be considered an *extreme* or *unique* case. Another use for a single-case design would be a *typical* or *representative* case, in which the researcher is highlighting an everyday situation. The caution here is for the researcher to be well informed enough to know what is typical or commonplace. A *revelatory* case is one in which researchers are able to observe a phenomenon that had been previously inaccessible. One other type of single case is the *longitudinal* case, meaning one in which researchers can examine the same entity over time to see changes that occur.

Whether to conduct a holistic design or an embedded design depends on whether researchers are looking at issues related globally to one entity or whether subcases within that entity must be considered. For example, in studying the effects of an educational policy on a large, urban public school district, researchers could use either type of design, depending on what they deem important to examine. If researchers focused on the global aspect of the policy and how it may have

changed the way the district structures its financial expenditures, the design would be holistic because the researcher would be exploring the entire school district to see effects. However, if the researcher examined the constraints placed on each regional subdivision within the district, each regional subdivision would become a subunit of the study as an embedded case design. Each regional office would be an embedded case and the district itself the major case. The researcher would procedurally examine each subunit and then reexamine the major case to see how the embedded subunits inform the whole case.

Multiple Case Design

Multiple cases have been considered by some to be a separate type of study, but Yin considers them a variant of single-case design and thus similar in methodological procedures. This design also may be called a *collective case*, *cross-case*, or *comparative case* study. From the previous example, a team of researchers might consider studying the financial decisions made by the five largest school districts in the United States since the No Child Left Behind policy went into effect. Under this design, the research team would study each of the largest districts as an individual case, either alone or with embedded cases within each district.

After conducting the analysis for each district, the team would further conduct analyses across the five cases to see what elements they may have in common. In this way, researchers would potentially add to the understanding of the effects of policy implementation among these large school districts. By selecting only the five largest school districts, the researchers have limited the findings to cases that are relatively similar. If researchers wanted to compare the implementation under highly varied circumstances, they could use *maximum variation selection*, which entails finding cases with the greatest variation. For example, they may establish criteria for selecting a large urban school district, a small rural district, a medium-sized district in a small city, and perhaps a school district that serves a Native American population on a reservation. By deliberately selecting from among cases that had potential for differing implementation due to their distinct contexts, the researchers expect to find as much variation as possible.

No matter what studies that involve more than a single case are called, what case studies have in common is that findings are presented as individual portraits that contribute to our understanding of the issues, first individually and then collectively. One question that often arises is whether the use of multiple cases can represent a form of generalizability, in

that researchers may be able to show similarities of issues across the cases. The notion of generalizability in an approach that tends to be qualitative in nature may be of concern because of the way in which one selects the cases and collects and analyzes the data. For example, in statistical studies, the notion of generalizability comes from the form of sampling (e.g., randomized sampling to represent a population and a control group) and the types of measurement tools used (e.g., surveys that use Likert-type scales and therefore result in numerical data). In case study research, however, Yin has offered the notion that the different cases are similar to multiple experiments in which the researcher selects among similar and sometimes different situations to verify results. In this way, the cases become a form of generalizing to a theory, either taken from the literature or uncovered and grounded in the data.

Nature of the Case Study

Another decision to be made in the design of a study is whether the purpose is primarily descriptive, exploratory, or explanatory. The nature of a descriptive case study is one in which the researcher uses *thick description* about the entity being studied so that the reader has a sense of having “been there, done that,” in terms of the phenomenon studied within the context of the research setting. Exploratory case studies are those in which the research questions tend to be of the *what can be learned about this issue* type. The goal of this kind of study is to develop working hypotheses about the issue and perhaps to propose further research. An explanatory study is more suitable for delving into *how and why* things are happening as they are, especially if the events and people involved are to be observed over time.

Case Study Approaches to Data

Data Collection

One of the reasons that case study is such a versatile approach to research is that both quantitative and qualitative data may be used in the study, depending on the research questions asked. While many case studies have qualitative tendencies, due to the nature of exploring phenomena in context, some case study researchers use surveys to find out demographic and self-report information as part of the study. Researchers conducting case studies tend also to use interviews, direct observations, participant observation, and source documents as part of the data analysis and interpretation. The documents may consist of archival records, artifacts, and websites that provide information about the

phenomenon in the context of what people make and use as resources in the setting.

Data Analysis

The analytic role of the researcher is to systematically review these data, first making a detailed description of the case and the setting. It may be helpful for the researcher to outline a chronology of actions and events, although in further analysis, the chronology may not be as critical to the study as the thematic interpretations. However, it may be useful in terms of organizing what may otherwise be an unwieldy amount of data.

In further analysis, the researcher examines the data, one case at a time if multiple cases are involved, for patterns of actions and instances of issues. The researcher first notes what patterns are constructed from one set of data within the case and then examines subsequent data collected within the first case to see whether the patterns are consistent. At times, the patterns may be evident in the data alone, and at other times, the patterns may be related to relevant studies from the literature. If multiple cases are involved, a cross-case analysis is then conducted to find what patterns are consistent and under what conditions other patterns are apparent.

Reporting the Case

While case study research has no predetermined reporting format, Stake has proposed an approach for constructing an outline of the report. He suggests that the researcher start the report with a vignette from the case to draw the reader into time and place. In the next section, the researcher identifies the issue studied and the methods for conducting the research. The next part is a full description of the case and context. Next, in describing the issues of the case, the researcher can build the complexity of the study for the reader. The researcher uses evidence from the case and may relate that evidence to other relevant research. In the next section, the researcher presents the *so what* of the case—a summary of claims made from the interpretation of data. At this point, the researcher may end with another vignette that reminds the reader of the complexity of the case in terms of realistic scenarios that readers may then use as a form of transference to their own settings and experiences.

Versatility

Case study research demonstrates its utility in that the researcher can explore single or multiple phenomena or multiple examples of one phenomenon. The researcher

can study one bounded entity in a holistic fashion or multiple subunits embedded within that entity. Through a case study approach, researchers may explore particular ways that participants conduct themselves in their localized contexts, or the researchers may choose to study processes involving program participants. Case study research can shed light on the particularity of a phenomenon or process while opening up avenues of understanding about the entity or entities involved in those processes.

CASE-ONLY DESIGN

Analytical studies are designed to test the hypotheses created by descriptive studies and to assess the cause-effect association. These studies are able to measure the effect of a specific exposure on the occurrence of an outcome over time. Depending on the nature of the exposure, whether it has been caused experimentally as an intervention on the study subjects or has happened naturally, without any specific intervention on the subjects, these studies may be divided into two major groups: *observational* and *experimental* studies. Each of these designs has its own advantages and disadvantages. In observational studies, by definition, the researcher is looking for causes, predictors, and risk factors by observing the phenomenon without doing any intervention on the subjects, whereas in experimental designs, there is an intervention on the study subjects. In practice, however, there is no clear-cut

distinction between different types of study design in biomedical research. *Case-only studies* are genetics studies in which individuals with and without a genotype of interest are compared, with an emphasis on environmental exposure.

For evaluation of etiologic and influencing role of some factors (such as risk factors) on the occurrence of diseases, we necessarily need to have a proper control group. Otherwise, no inferential decision can properly be made on the influencing role of risk factors. One of the study designs with control subjects is *case-control* study. These studies are designed to assess the cause-effect association by comparing a group of patients with a (matched) group of control subjects in terms of influencing or etiologic factors.

Some concerns in case-control studies, including control group and appropriate selection of control subjects, expensive cost for examining risk markers in both cases and controls (particularly in genetic studies), and the time-consuming process of such studies, have led to the development of the *case-only* method in studying the gene-environment interaction in human diseases. Investigators studying human malignancies have broadly used this method in recent years.

The case-only method was originally designed as a valid approach to the analysis and screening of genetic factors in the etiology of multifactorial diseases and also to assessing the gene-environment interactions in the etiology. In a case-only study, cases with and without the susceptible genotype are compared with each other in terms of the existence of the environmental exposure.

To conduct a case-only design, one applies the same epidemiological approaches to case selection rules as for any case-control study. The case-only study does not, however, have the complexity of rules for the selection of control subjects that usually appears in traditional case-control studies. The case-only method also requires fewer cases than the traditional case-control study. Furthermore, the case-only design has been reported to be more efficient, precise, and powerful compared with a traditional case-control method.

Although the case-only design was originally created to improve the efficiency, power, and precision of the study of the gene-environment interactions by examining the prevalence of a specific genotype among case subjects only, it is now used to investigate how some other basic characteristics that vary slightly (or never vary) over time (e.g., gender, ethnicity, marital status, social and economic status) modify the effect of a time-dependent exposure (e.g., air pollution, extreme temperatures) on the outcome (e.g., myocardial infarction, death) in a group of cases only (e.g., decedents).

To avoid misinterpretation and bias, some technical assumptions should be taken into account in case-only studies. The assumption of independence between the susceptibility genotypes and the environmental exposures of interest in the population is the most important one that must be considered in conducting these studies. In practice, this assumption may be violated by some confounding factors (e.g., age, ethnic groups) if both exposure and genotype are affected. This assumption can be tested by some statistical methods. Some other technical considerations also must be assumed in the application of the case-only model in various studies of genetic factors. More details of these assumptions and the assessment of the gene–environment interaction in case-only studies can be found elsewhere.

CATEGORICAL DATA ANALYSIS

A categorical variable consists of a set of nonoverlapping categories. Categorical data are *counts* for those categories. The measurement scale of a categorical variable is *ordinal* if the categories exhibit a natural ordering, such as opinion variables with categories from “strongly disagree” to “strongly agree.” The measurement scale is

nominal if there is no inherent ordering. The types of possible analysis for categorical data depend on the measurement scale.

Types of Analysis

When the subjects measured are cross-classified on two or more categorical variables, the table of counts for the various combinations of categories is a *contingency table*. The information in a contingency table can be summarized and further analyzed through appropriate *measures of association* and models as discussed below. These measures and models differentiate according to the nature of the classification variables (nominal or ordinal).

Most studies distinguish between one or more *response variables* and a set of *explanatory variables*. When the main focus is on the association and interaction structure among a set of response variables, such as whether two variables are conditionally independent given values for the other variables, *loglinear models* are useful, as described in a later section. More commonly, research questions focus on effects of explanatory variables on a categorical response variable. Those explanatory variables might be categorical, quantitative, or of both types. *Logistic regression models* are then of particular interest. Initially such models were developed for *binary* (success–failure) response variables. They describe the *logit*, which is $\log[P(Y = 1) / P(Y = 2)]$, using the equation

$$\log[P(Y = 1) / P(Y = 2)] = a + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p,$$

where Y is the binary response variable and $x_1, \dots, x_p$ the set of the explanatory variables. The logistic regression model was later extended to nominal and ordinal response variables. For a nominal response Y with J categories, the model simultaneously describes

$$\begin{aligned} &\log[P(Y = 1) / P(Y = J)], \\ &\log[P(Y = 2) / P(Y = J)], \dots, \\ &\log[P(Y = J - 1) / P(Y = J)]. \end{aligned}$$

For ordinal responses, a popular model uses explanatory variables to predict a logit defined in terms of a cumulative probability,

$$\log[P(Y \leq j) / P(Y > j)], j = 1, 2, \dots, J - 1.$$

For categorical data, the binomial and multinomial distributions play the central role that the normal does for quantitative data. Models for categorical data assuming the binomial or multinomial were unified with standard regression and *analysis of variance* (ANOVA) models for quantitative data assuming

normality were unified through the introduction of the *generalized linear model* (GLM). This very wide class of models can incorporate data assumed to come from any of a variety of standard distributions (such as the normal, binomial, and Poisson). The GLM relates a function of the mean (such as the log or logit of the mean) to explanatory variables with a linear predictor. Certain GLMs for counts, such as *Poisson regression* models, relate naturally to log linear and logistic models for binomial and multinomial responses.

More recently, methods for categorical data have been extended to include *clustered data*, for which observations within each cluster are allowed to be correlated. A very important special case is that of *repeated measurements*, such as in a longitudinal study in which each subject provides a cluster of observations taken at different times. One way this is done is to introduce a *random effect* in the model to represent each cluster, thus extending the GLM to a *generalized linear mixed model*, the *mixed* referring to the model's containing both random effects and the usual sorts of fixed effects.

Two-Way Contingency Tables

Two categorical variables are *independent* if the probability of response in any particular category of one variable is the same for each category of the other variable. The most well-known result on two-way contingency tables is the test of the null hypothesis of independence, introduced by Karl Pearson in 1900. If X and Y are two categorical variables with I and J categories, respectively, then their cross-classification leads to a $I \times J$ table of observed frequencies $n = (n_{ij})$. Under this hypothesis, the expected cell frequencies are values that have the same marginal totals as the observed counts but perfectly satisfy the hypothesis. They equal $m_{ij} = n\pi_{i+}\pi_{+j}$, $i = 1, \dots, I$, $j = 1, \dots, J$, where n is the total sample size ($n = \sum_{i,j} n_{ij}$) and π_{i+} (π_{+j}) is the i th row (j th column) marginal of the underlying probabilities matrix $\pi = (\pi_{ij})$. Then the corresponding maximum likelihood (ML) estimates equal $\hat{m}_{ij} = np_{i+}p_{+j} = \frac{n_{i+}n_{+j}}{n}$, where p_{ij} denotes the sample proportion in cell (i, j) . The hypothesis of independence is tested through Pearson's chi-square statistic,

$$X^2 = \sum_{i,j} \frac{(n_{ij} - \hat{m}_{ij})^2}{\hat{m}_{ij}}. \quad (1)$$

The p value is the right-tail probability above the observed X^2 value. The distribution of X^2 under the null hypothesis is approximated by a $\chi^2_{(I-1)(J-1)}$, provided that the individual expected cell frequencies are not too small. In fact, Pearson claimed that the

associated degrees of freedom (df) were $IJ - 1$, and R. A. Fisher corrected this in 1922. Fisher later proposed a small-sample test of independence for 2×2 tables, now referred to as *Fisher's exact test*. This test was later extended to $I \times J$ tables as well as to more complex hypotheses in both two-way and multiway tables. When a contingency table has ordered row or column categories (ordinal variables), specialized methods can take advantage of that ordering.

Ultimately more important than mere testing of significance is the estimation of the strength of the association. For ordinal data, measures can incorporate information about the direction (positive or negative) of the association as well.

More generally, models can be formulated that are more complex than independence, and expected frequencies m_{ij} can be estimated under the constraint that the model holds. If $\hat{m}_{ij}$ are the corresponding maximum likelihood estimates, then, to test the hypothesis that the model holds, one can use the Pearson statistic (Equation 1) or the statistic that results from the standard statistical approach of conducting a *likelihood-ratio test*, which is

$$G^2 = 2 \sum_{i,j} n_{ij} \ln \left(\frac{n_{ij}}{\hat{m}_{ij}} \right). \quad (2)$$

Under the null hypothesis, both statistics have the same large-sample chi-square distribution.

The special case of the 2×2 table occurs commonly in practice, for instance for comparing two groups on a success/fail-type outcome. In a 2×2 table, the basic measure of association is the *odds ratio*. For the probability table

$$\begin{bmatrix} \pi_{11} & \pi_{12} \\ \pi_{21} & \pi_{22} \end{bmatrix}$$

the odds ratio is defined as $\theta = \frac{\pi_{11}\pi_{22}}{\pi_{12}\pi_{21}}$. Independence corresponds to $\theta = 1$.

Inference about the odds ratio can be based on the fact that for large samples,

$$\log(\hat{\theta}) \sim N \left(\log(\theta), \frac{1}{n_{11}} + \frac{1}{n_{12}} + \frac{1}{n_{21}} + \frac{1}{n_{22}} \right).$$

The odds ratio relates to the *relative risk* r . In particular, if we assume that the rows of the above 2×2 table represent two independent groups of subjects (A and B) and the columns correspond to presence/absence of a disease, then the relative risk for this disease is defined as $r = \frac{\pi_A}{\pi_B}$, where $\pi_A = \frac{\pi_{11}}{\pi_{1+}}$ is the

probability of disease for the first group and π_B is defined analogously. Since $\theta = r \frac{1-\pi_B}{1-\pi_A}$, it follows that $\theta \approx r$ whenever π_A and π_B are close to 0.

Models for Two-Way Contingency Tables

Independence between the classification variables X and Y (i.e., $m_{ij} = n\pi_{i+}\pi_{+j}$, for all i and j) can equivalently be expressed in terms of a log linear model as

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y, \\ i = 1, \dots, I, j = 1, \dots, J.$$

The more general model that allows association between the variables is

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_{ij}^{XY}, \\ i = 1, \dots, I, j = 1, \dots, J. \quad (3)$$

Loglinear models describe the way the categorical variables and their association influence the count in each cell of the contingency table. They can be considered as a discrete analogue of ANOVA. The two-factor interaction terms relate to odds ratios describing the association. As in ANOVA models, some parameters are redundant in these specifications, and software reports estimates by assuming certain constraints.

The general model (Equation 3) does not impose any structure on the underlying association, and so it fits the data perfectly. Associations can be modeled through *association models*. The simplest such model, the *linear-by-linear association model*, is relevant when both classification variables are ordinal. It replaces the interaction term λ_{ij}^{XY} by the product $\phi\mu_i\nu_j$, where μ_i and ν_j are known scores assigned to the row and column categories, respectively. This model,

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y + \phi\mu_i\nu_j, \\ i = 1, \dots, I, j = 1, \dots, J, \quad (4)$$

has only one parameter more than the independence model, namely ϕ . Consequently, the associated df are $(I-1)(J-1)-1$, and once it holds, independence can be tested conditionally on it by testing $\phi = 0$ via a more powerful test with $df = 1$. The linear-by-linear association model (Equation 4) can equivalently be expressed in terms of the $(I-1)(J-1)$ local odds ratios

$$\theta_{ij} = \frac{\pi_{ij}\pi_{i+1,j+1}}{\pi_{i,j+1}\pi_{i+1,j}} \quad (I = 1, \dots, I-1, j = 1, \dots, J-1), \text{ defined by adjacent rows and columns of the table:}$$

$$\theta_{ij} = \exp[\phi(\mu_{i+1} - \mu_i)(\nu_{j+1} - \nu_j)], \\ i = 1, \dots, I-1, j = 1, \dots, J-1. \quad (5)$$

With equally spaced scores, all the local odds ratios are identical, and the model is referred to as *uniform association*. More general models treat one or both sets of scores as parameters. Association models have been mainly developed by L. Goodman.

Another popular method for studying the pattern of association between the row and column categories of a two-way contingency table is *correspondence analysis* (CA). It is mainly a descriptive method. CA assigns optimal scores to the row and column categories and plots these scores in two or three dimensions, providing thus a reduced rank display of the underlying association.

The special case of square $I \times I$ contingency tables with the same categories for the rows and the columns occurs with matched-pairs data. For example, such tables occur in the study of *rater agreement* and in the analysis of social mobility. A condition of particular interest for such data is *marginal homogeneity*, that $\pi_{i+} = \pi_{+i}, i = 1, \dots, I$. For the 2×2 case of binary matched pairs, the test comparing the margins using the chi-square statistic $(n_{12} - n_{21})^2 / (n_{12} + n_{21})$ is called *McNemar's test*.

Multiway Contingency Tables

The models described earlier for two-way tables extend to higher dimensions. For multidimensional tables, a number of models are available, varying in terms of the complexity of the association structure. For three variables, for instance, models include ones for which (a) the variables are mutually independent; (b) two of the variables are associated but are jointly independent of the third; (c) two of the variables are conditionally independent, given the third variable, but may both be associated with the third; and (d) each pair of variables is associated, but the association between each pair has the same strength at each level of the third variable. Because the number of possible models increases dramatically with the dimension, model selection methods become more important as the dimension of the table increases. When the underlying theory for the research study does not suggest particular methods, one can use the same methods that are available for ordinary regression models, such as stepwise selection methods and fit indices such as Akaike Information Criterion.

Loglinear models for multiway tables can include higher order interactions up to the order equal to the dimension of the table. Two-factor terms describe

conditional association between two variables, three-factor terms describe how the conditional association varies among categories of a third variable, and so forth. CA has also been extended to higher dimensional tables, leading to *multiple CA*.

Historically, a common way to analyze higher way contingency tables was to analyze all the two-way tables obtained by collapsing the table over the other variables. However, the two-way associations can be quite different from conditional associations in which other variables are controlled. The association can even change direction, a phenomenon known as *Simpson's paradox*. Conditions under which tables can be collapsed are most easily expressed and visualized using graphical models that portray each variable as a node and a conditional association as a connection between two nodes. The patterns of associations and their strengths in two-way or multiway tables can also be illustrated through special plots called *mosaic plots*.

Inference and Software

Least squares is not an optimal estimation method for categorical data, because the variance of sample proportions is not constant but rather depends on the corresponding population proportions. Because of this, parameters for categorical data were estimated historically by the use of *weighted least squares*, giving more weight to observations having smaller variances. Currently, the most popular estimation method is *maximum likelihood*, which is an optimal method for large samples for any type of data. The *Bayesian* approach to inference, in which researchers combine the information from the data with their prior beliefs to obtain posterior distributions for the parameters of interest, is becoming more popular. For large samples, all these methods yield similar results.

Standard statistical packages, such as SAS, SPSS (an IBM company, formerly called PASW® Statistics), Stata, and S-Plus and R, are well suited for analyzing categorical data. Such packages now have facility for fitting GLMs, and most of the standard methods for categorical data can be viewed as special cases of such modeling. Bayesian analysis of categorical data can be carried out through WINBUGS. Specialized software such as the programs StatXact and LogXact, developed by Cytel Software, are available for small-sample exact methods of inference for contingency tables and for logistic regression parameters.

CATEGORICAL STRUCTURAL EQUATION MODELING

Structural equation modeling (SEM; also known as *covariance structure analysis* or *latent variable analysis*) belongs to the family of two statistical models and techniques of multivariate data analysis, based on interdependence technique (factor analysis [FA]) and dependence (multiple regression analysis [MRA]). It represents a unique combination, in which FA explores the interdependence of observed variables (indicators, items) and develops theoretical constructs (latent—or unobserved—variables), while the MRA (i.e., SEM) explains their mutual relationships. In particular, SEM aims to test the hypothesized causal relationships between the dependent (exogenous) latent variables and independent (endogenous) latent variables that are reflected in theoretical constructs and developed in the process of operationalization, based on data derived from, for example, tests, measurement scales, self-reports, or questionnaires. Examples of theoretical constructs include intelligence, anxiety, personality, human values, satisfaction, and compulsive buying. Due to complexity, the constructs remain unobservable

but can be measured indirectly and transformed mathematically into latent variables.

Latent variables are the next inherent parts of the SEM model; they “participate” in testing the plausibility of hypothetical assertions about potential relationships among the specified latent variables. Thus, in SEM, the researcher conducts observation of causal effects between designated latent variables, according to theory and the researcher’s own vision of model configuration. A process of developing latent variables and further stage of testing their relationships may be defined as a two-stage approach—that is, the researcher conducts first the operations of measurement by linking observed variables to latent variables (confirmatory factor analysis [I]CFA). Second, the researcher develops SEM models by linking latent variables via systems of simultaneous equations. The researcher uses CFA to examine patterns and quality of interrelationships among latent variables with adhered observed variables.

This entry first reviews the theory in and features of SEM and then explores the categorical approach to SEM, including problems and recommendations for applying estimators in categorical data and SEM.

The Importance of Theory in SEM

Although the general idea of the SEM model aims to confirm or reject proposed theory, assuming the explanatory power of relationships among latent variables, based typically on continuous data, SEM provides statistical, specific estimates of the strength of all

hypothesized relationships in a theoretical model—either directly, from one variable to another, or via other variables (i.e., intervening or mediating variables) positioned between the other two. The postulated relationships must be preceded by theory. Without explicit theoretical background, the researcher usually encounters problems with finding the most optimal relationships among a set of latent variables, as there are usually numerous alternative ways of depicting the relationships. Thereby, prior to constructing a SEM model, one must precisely diagnose research problems and find accurate, logic relationships between the latent variables. Without it, even “small” errors in positioning latent variables or an assumption of misleading relationships (where paths denote hypothesized relationships) can create havoc all over a model and result in the solution suggesting erroneous inferences. Thus, theory should be a starting point in every process of SEM (see Figure 1), where structural equations are perceived as one-to-one representation of the theory.

In the next phase of the SEM process, a sample is designed and measures are obtained on the basis of the sample. This is followed by the estimation of the parameters of the model. At this stage, the measurement parts (CFA) of the SEM model can be estimated first, followed by the structural model (SEM), or the full model (comprising both CFA and SEM parts) can be estimated at once. Concurrently, the researcher assesses the goodness of fit of the model and if necessary, considers the possibility of modification. In consequence, this process may assume a cyclical form (see Figure 1); the SEM model can be modified and

Figure 1 Typical Process of Structural Equation Modeling (SEM)

Figure 2 An Example of Configuration of the General, Full SEM Latent Variable Model

Note: Area denoted as rectangle with dashed line represents structural part of SEM model. Mathematical notations: Black ellipse defines independent (exogenous) latent (unobserved) variable ξ_1 (gr. *ksi*); white ellipse represents dependent (endogenous) latent (unobserved) variable η_1 (gr. *eta*); squares in gray color denote observed variables (indicators) X (gr. *chi*) of independent latent variable, e.g. ξ_1 ; squares in white color denote observed variables (indicators) Y (gr. *ipsylon*) of dependent latent variable, e.g. η_1 ; disturbances ζ (gr. *dzeta*) pertain to dependent (endogenous) latent variable η ; measurement errors δ (gr. *delta*) are directed at X observed variables; measurement errors ε (gr. *epsilon*) are directed at Y observed variables; factor loadings λ^X (gr. *lambda*) defining relations between independent (exogenous) latent variables ξ and observed variables X ; factor loadings λ^Y defining relations between independent (endogenous) latent variable η and observed variables Y ; coefficient β_{21} (direct effect)—*beta* (gr.) examining the relationship of endogenous variable η_1 on endogenous variable η_2 ; coefficient γ_{12} *gamma* (gr.)—as the main direct effect/influence of exogenous variable ξ_1 on endogenous variable η_2 , and signs (+) or (–) denote type of assumed relationship: positive or negative.

evaluated in terms of goodness of fit, until a decision is made that it meets some standard of adequate fit. However, all imposed modifications need justification on theoretical grounds. In the end, the researcher conducts discussion of all results. An example of the configuration of the SEM model, comprising the measurement and structural part, is presented in Figure 2.

Important Features of SEM

Overall, SEM, as the analytical strategy, can be prospectively applied in many different sciences. The main reason is that it provides researchers with a comprehensive analytical solution for the quantification and testing of theories. SEM can be distinguished by three

fundamental characteristics: (1) estimation of relationships via multiple systems of simultaneous equations; (2) representation of unobserved theoretical concepts (latent variables) in these relationships; and (3) representation of measurement errors through the use of multiple indicator latent variables. SEM also permits complicated relationships to be expressed via hierarchical or nonhierarchical, recursive or nonrecursive structural equations, which consequently present a more complete picture of the tested theory and reality. It is a statistical strategy that focuses on the confirmatory approach (hypothesis testing), by demanding specific patterns of relations to be specified a priori; thus, SEM lends itself well to the analysis of data for inferential purposes. Moreover, SEM allows researchers to assess or correct measurement errors; the SEM model

provides explicit estimates of the error variance parameters. Furthermore, in advanced configurations, SEM offers a possibility of diagnosing group similarities based on multigroup SEM diagnostics, which test equivalence of the model parameters across groups, such as factor loadings and structural path coefficients. SEM also allows for estimation of direct or indirect effects (i.e., complex mediational mechanisms through the decomposition of effects), as well as for the testing of moderation mechanisms through the application of various traits, such as age, gender, and education, to name a few. Lastly, SEM can be extended toward the latent growth curve modeling to examine the repeated measures from longitudinal research projects. The other developments in SEM are developed on the ground of categorical variable methodology (CVM).

Categorical Approach to SEM

While the assumptions underlying the popular normal theory estimators used in SEM are important, in empirical research, specifically in the social sciences, there appears the prevalence of categorical and non-normal data. The data required by normal theory estimators, used in SEM, must be continuous by nature, while theoretical constructs must be multivariate normally distributed in the population. The two most common used estimators in normal theory and in SEM (maximum likelihood [ML] and generalized least squares) require multivariate normal distribution of variables; however, the categorical data (based, e.g., on Likert-type data, ordered responses) are discrete in nature, therefore cannot by definition be normally distributed. Although some researchers treat these data as continuous, the measurements are “coarse” and often produce misleading results. Given these facts, in theory of latent variable models and SEM, alternative analytical solutions (i.e., forms of model specification and estimation procedures associated with CVM) have been proposed. Given their wide scope, only the most important solutions are discussed in this entry.

Specification of SEM Measurement Model Based on Categorical Data

When the structural model (SEM) is considered, it may take the same form regardless of response type; however, when observed variables are categorical, the conventional measurement model must be modified according to the CVM. In case of the SEM based on categorical data (e.g., ordinal responses), the measurement model is specified from the perspective of multivariate normal latent responses (i.e., underlying

variables), instead of observed continuous responses, as it is in the conventional approach to SEM. The latent responses are then linked to observed categorical responses via thresholds in the model, generating a new variant of the measurement model. In this regard, an important fact is that each observed categorical response is related to a latent continuous response via a threshold model. In sum, when we assume the following conventional approach in specification of the structural model for latent variables (e.g., η_j)

$$\eta_j = \alpha + B_{\eta_j} + \Gamma_{X_{1j}} + \zeta_j. \quad (1)$$

where α denotes an intercept vector, B is matrix of structural parameters reflecting the postulated theoretical relationships among the latent variables, Γ defines a regression parameter matrix of regression of latent variables on observed variables X_{1j} , and ζ_j is the vector of disturbances.

The measurement model specified for latent continuous responses y_j^* (in contrast to observed continuous responses y_j) will assume the following structure:

$$y_j^* = v + \Lambda_{\eta_j} + K_{X_{2j}} + \epsilon_j. \quad (2)$$

where v denotes vector of intercepts, Λ is a factor loading matrix, and ϵ refers to vector of measurement errors. The additional term $K_{X_{2j}}$ represents a regression parameter matrix for the regression of y_j^* on observed variables X_{2j} . Note also that, when this model is combined with threshold solution, it turns into a probit model.

Given the thresholds assumed in the model, each observed categorical response y_{ij} is related to a latent continuous response y_{ij}^* . For example, a measurement model containing ordinal observed responses (i.e., data obtained from the use of Likert-type scale based on five response choices) generates only four threshold values (the number of thresholds is equal to the number of categories less one) that are needed to divide continuous latent response variable into five ordered categories. Thus, the observed ordinal data y_{ij} can be explained as follows:

$$y_{ij} = \begin{cases} 1 & \text{if } y_{ij}^* \leq \kappa_{1i} \\ 2 & \text{if } \kappa_{1i} \leq y_{ij}^* \leq \kappa_{2i} \\ 3 & \text{if } \kappa_{2i} \leq y_{ij}^* \leq \kappa_{3i} \\ 4 & \text{if } \kappa_{3i} \leq y_{ij}^* \leq \kappa_{4i} \\ 5 & \text{if } y_{ij}^* > \kappa_{4i} \end{cases}. \quad (3)$$

Based on such specification of thresholds (assuming a five-point Likert-type scale), the observed ordinal-level data are only reported as discrete values from 1 to 5; however, the “true levels” of the latent response

variable y_{ij}^* appear to be more precise than allowed by this scale. Thereby, the observed data can be explained in terms of an approximation of the underlying continuous latent response variable. Note also that the difference between latent and observed data generates two important effects when we model the data. First, unlike y_{ij}^* , the standard linear model of measurement, as it occurs in classical SEM, does not hold validity. Second, the estimated model, based on assumption that structure in the population $\Sigma = \Sigma(0)$ does not hold accuracy in case of discrete data.

Finally, to fix problems with mixed types of response (either continuous or categorical-dichotomous observed responses), theory proposes the generalized latent variable measurement model:

$$\mathbf{g}(\boldsymbol{\mu}_j) = \mathbf{v} + \boldsymbol{\Lambda}_{\eta_j} + \mathbf{K}_{\mathbf{X}_{2j}} \quad (4)$$

where $\mathbf{g}$ denotes vector of link function based on various response types, while $\boldsymbol{\mu}_j$ represents vector of conditional means of the responses η_j and $\mathbf{X}_{2j}$. As can be observed in Equation 4, there are no measurement errors, because the variability level of responses is based on the conditional response distributions.

Problems With Modeling Categorical Data and Estimation in SEM

When modeling categorical data (e.g., ordinal data) with SEM, researchers often ignore their categorical nature and apply the ML estimator, treating the data as continuous. However, the decision of whether or not to apply ML estimator depends on specific conditions, such as number of used categories and distribution of examined variables. As the number of categories is reduced, the effect is fewer response choices available for respondents to choose, and the greater attenuation in responses. Thus, with ML estimation, it becomes less likely that observed data will at least approximate a normal distribution. With few categories, the model fit indices, parameter estimates, and standard errors are always biased. In contrast, as the number of categories increases, the obtained estimates are closer to their true values, and the greater the consistency between true and obtained values. Therefore, if data have many categories (e.g., at least five) and are approximately normal, the use of ML estimator will not lead to severe levels of bias in the model fit indices, parameter estimates, and standard errors, although a caution must be maintained in interpretation of results.

Overall, in contrast to the multinormally distributed continuous responses, ML estimation cannot be efficiently based on statistics such as the empirical covariance matrix (and possibly mean vector) of the observed

responses. Instead, the likelihood must be generated indirectly by “integrating out” the latent variables. For the special case of models with multinormal latent responses (i.e., principally probit models), theory has proposed a computationally efficient limited information estimation approach. For example, when we consider SEM based on dichotomous responses and no observed explanatory variables, the estimation will proceed by first estimating tetrachoric correlations (pairwise correlations between the latent responses), and then the asymptotic covariance matrix of the tetrachoric correlations will be estimated. In the end, the parameters of SEM may be estimated using weighted least squares (see next section), fitting model-implied to estimated tetrachoric correlations, where the inverse of the asymptotic covariance matrix of the tetrachoric correlations may serve as weight matrix.

Selected Estimation Strategies Addressed to Categorical Data in SEM

To overcome obstacles with non-normal and categorical data, the *asymptotic distribution free* estimator (ADF; or *weighted least squares* [WLS]) can be applied; or alternatively, one can use the *Satorra–Bentler* (S-B) *scaling procedure* to adjust chi-square statistic and standard errors in the ML estimator. The ADF is free from meeting the assumption of normality; the input matrices are employed to fix the issues of parameter estimate attenuation associated with a small number of categories, as part of discrete data. A problem with ADF is that it requires large samples (e.g., 2,000, 3,000) in research designs. Because of the inverse of the weight matrix, which needs to be calculated, a large weight matrix makes ADF estimation computationally intensive (e.g., with only 10 observed variables, and the dimensions of weight matrix 55×55 , one needs 3,025 elements). Thus, ADF requires large sample size for results to converge to stable results. Note however that, in ADF estimation, the CVM may incorporate the assumptions of the metric of the data into SEM analyses by considering two components: input for analyses that recognizes the ordered categorical observed variables; and the use of the correct weight matrix when employing ADF. In the end, categorical data may be part of the ADF estimation procedure, assuming specific input to accommodate categorical variables (e.g., ordered responses from Likert-type scale).

Another solution that can be used to handle problems with non-normal distribution of the data or in diagnosis of categorical data is the S-B scaling procedure, whereby the researcher corrects the fit indices, and standard errors by factor based on the amount of non-normality in these data. This procedure is applied

within the range of ML estimation to better approximate the theoretical chi-square reference distribution. In contrast to the ADF estimator, the S-B does not require inversion of the large asymptotic covariance matrix; consequently, the matrices, which must be inverted in order to compute the scaling factor, are of the smaller dimensions—computation problems and large sample sizes experienced with the ADF estimation are simply avoided. A similar scaling process is applied to adjust the standard errors, which are corrected upward to approximate those that would be obtained if the data were normally distributed. Numerous researches confirmed the adequacy of S-B correction in case of categorical (e.g., ordered) data, establishing that this strategy treats the categorical data as continuous, ignoring the metric level of the data. There is only one caution when this approach is applied: the ML estimation may be sensitive to the number of response categories in addition to non-normal distributions.

In SEM based on CVM, one has also estimators known as *weighted least squares mean adjusted* (WLSM), *weighted least squares mean and variance adjusted* (WLSMV), which also avoid the necessity of a large sample size (as in case of the ADF estimator) by decreasing the computational intensity, and incorporating similar to S-B, scaling approach. In comparison to the ADF, the WLSM and WLSMV solutions do not need to use the full matrix in estimating parameters, but use only the diagonal elements of the weight matrix (e.g., the asymptotic variances of the thresholds and latent correlation estimates). On the other hand, to compute standard errors for these parameters, the WLSM and WLSMV use the entire weight matrix, but simultaneously employ an approach that avoids its inversion. The chi-square value of the estimated model is obtained by calculation of the full weight matrix, which also skips the inversion. Moreover, both estimators employ a scaling factor to adjust chi-square value by mean (WLSM) or by mean and variance (WLSMV). Empirical studies have shown that WLSM and WLSMV estimators outperform the ADF when the postulated model is large (e.g., 15 variables) and when sample size equals, for example, $N = 1,000$, leading to less biased chi-square and standard errors. Also, the WLSMV (compared to the WLSM) shows lower Type I error rates and behaves generally well except under conditions of small sample sizes ($N = 200$) and markedly skewed variables.

Finally, for scales using five or more categories, when the data are non-normally distributed, beyond the S-B procedure, there exists *bootstrap resampling*. This approach, instead of using the theoretical sampling distribution and adjusting the obtained chi-square value for the non-normality of the data,

constructs an empirical distribution of model test statistics that incorporates the non-normality of the data and does not require the theoretical chi-square distribution. Technically speaking, in bootstrap resampling, the observed data can be treated as the estimate of the population. However, to obtain this effect, the researcher must draw first a large number of cases, with replacement, from the sample data. Having prepared numerous subsamples (bootstrap samples), the researcher can calculate the general statistic of interest from each subsample; the estimates obtained from each subsample form an empirical sampling distribution of the statistic of interest.

Recommendations for Application of Estimators in Categorical Data and SEM

Overall, the selection of appropriate analytical strategy (estimation), assuming the categorical nature of data, depends on the number of response categories used in scale, degree of non-normality, and crudeness of categorization. For instance, when a researcher is modeling the categorical data and the observed variables, which reflect at least five categories (the ordinal nature of responses from Likert-type scale), but the data are not approximately normally distributed, then S-B scaling or bootstrapping solutions should be applied. On one hand, if categorical variables have fewer categories than five, the robust estimators (WLSM, WLSMV) can be applied. On the other hand, given the requirements of the ADF, as large sample size, or the lack of sensitivity to model misspecification, this estimator will not always perform well in SEM. Note also that, due to mathematical complexity of estimating and testing SEM models using categorical data, application of statistical software is a must. In particular, to conduct analysis based on the ADF, one can use the following popular computer programs: LISREL, EQS, Mplus, or AMOS. The S-B scaling procedure can be performed with EQS or Mplus, whereas the robust estimators (WLSM and WLSMV) are available in Mplus. Finally, bootstrapping can be conducted with EQS, Mplus, AMOS, and LISREL.

CATEGORICAL VARIABLE

Categorical variables are qualitative data in which the values are assigned to a set of distinct groups or categories. These groups may consist of alphabetic (e.g., male, female) or numeric labels (e.g., male = 0, female = 1) that do not contain mathematical information beyond the frequency counts related to group membership. Instead, categorical variables often provide valuable social-oriented information that is not quantitative by nature (e.g., hair color, religion, ethnic group).

In the hierarchy of measurement levels, categorical variables are associated with the two lowest variable classification orders, nominal or ordinal scales, depending on whether the variable groups exhibit an intrinsic ranking. A nominal measurement level consists purely of categorical variables that have no ordered structure for intergroup comparison. If the categories can be

ranked according to a collectively accepted protocol (e.g., from lowest to highest), then these variables are ordered categorical, a subset of the ordinal level of measurement.

Categorical variables at the nominal level of measurement have two properties. First, the categories are mutually exclusive. That is, an object can belong to only one category. Second, the data categories have no logical order. For example, researchers can measure research participants' religious backgrounds, such as Jewish, Protestant, Muslim, and so on, but they cannot order these variables from lowest to highest. It should be noted that when categories get numeric labels such as male = 0 and female = 1 or control group = 0 and treatment group = 1, the numbers are merely labels and do not indicate one category is "better" on some aspect than another. The numbers are used as symbols (codes) and do not reflect either quantities or a rank ordering. *Dummy coding* is the quantification of a variable with two categories (e.g., boys, girls). Dummy coding will allow the researcher to conduct specific analyses such as the *point-biserial correlation coefficient*, in which a dichotomous categorical variable is related to a variable that is continuous. One example of the use of point-biserial correlation is to compare males with females on a measure of mathematical ability.

Categorical variables at the ordinal level of measurement have the following properties: (a) the data categories are mutually exclusive, (b) the data categories have some logical order, and (c) the data categories are scaled according to the amount of a particular characteristic. Grades in courses (i.e., A, B, C, D, and F) are an example. The person who earns an A in a course has a higher level of achievement than one who gets a B, according to the criteria used for measurement by the course instructor. However, one cannot assume that the difference between an A and a B is the same as the difference between a B and a C. Similarly, researchers might set up a Likert-type scale to measure level of satisfaction with one's job and assign a 5 to indicate *extremely satisfied*, 4 to indicate *very satisfied*, 3 to indicate *moderately satisfied*, and so on. A person who gives a rating of 5 feels more job satisfaction than a person who gives a rating of 3, but it has no meaning to say that one person has 2 units more satisfaction with a job than another has or exactly how much more satisfied one is with a job than another person is.

In addition to verbal descriptions, categorical variables are often presented visually using tables and charts that indicate the group frequency (i.e., the number of values in a given category). Contingency tables show the number of counts in each category and increase in complexity as more attributes are examined for the same object. For example, a car can be classified

according to color, manufacturer, and model. This information can be displayed in a contingency table showing the number of cars that meet each of these characteristics (e.g., the number of cars that are white and manufactured by General Motors). This same information can be expressed graphically using a bar chart or pie chart. Bar charts display the data as elongated bars with lengths proportional to category frequency, with the category labels typically being the x-axis and the number of values the y-axis. On the other hand, pie charts show categorical data as proportions of the total value or as a percentage or fraction. Each category constitutes a section of a circular graph or “pie” and represents a subset of the 100% or fractional total. In the car example, if 25 cars out of a sample of 100 cars were white, then 25%, or one quarter, of the circular pie chart would be shaded, and the remaining portion of the chart would be shaded alternative colors based on the remaining categorical data (i.e., cars in colors other than white).

Specific statistical tests that differ from other quantitative approaches are designed to account for data at the categorical level. The only *measure of central tendency* appropriate for categorical variables at the nominal level is *mode* (the most frequent category or categories if there is more than one mode), but at the ordinal level, the median or point below which 50% of the scores fall is also used. The chi-square distribution is used for categorical data at the nominal level. Observed frequencies in each category are compared with the theoretical or expected frequencies. Types of correlation coefficients that use categorical data include point biserial; Spearman rho, in which both variables are at the ordinal level; and phi, in which both variables are dichotomous (e.g., boys vs. girls on a yes–no question). Categorical variables can also be used in various statistical analyses such as *t* tests, analysis of variance, multivariate analysis of variance, simple and multiple regression analysis, and discriminant analysis.

CATEGORIZING CONTINUOUS DATA

Researchers sometimes wish to report or analyze a continuous variable by recoding a range of values into a few categories, such as taking all the scores from a test and categorizing them as high or low. This can be a valuable way to improve the interpretation of data but is often not recommended for statistical analysis, where the most precise measurements enable the most robust statistical tests to be deployed. This entry first discusses continuous and categorical variables and then provides an example to illustrate the use of transformed categorical variables.

Continuous Variables

Quantitative research uses numbers to represent the values of a variable, for instance age. For example, age is a variable because it can *vary* from one participant to the next within a sample. Many variables are preexisting known measurements, such as age in years, length of an object in centimeters, distance in kilometers, and time in minutes or seconds. Variables are considered as continuous variables when there is a range of numbers or scores that can represent the concept. For age, it would be age in years, where the value for that variable might be anywhere from 0–130 years of age, with every value in between being a possible value for that variable.

Other concepts have numeric values assigned to them, such as when participants in a study answer questions on an instrument, and their responses are allocated numbers, to calculate a composite score for the instrument. Responses to the questions on the questionnaire (or more technically called *items* on an *instrument*) are each allocated a numerical value. For instance, a Likert-type scale item asks respondents to select from a range of choices regarding how much they agree or disagree with a given statement. “I love numbers” could be the statement, and a response of *strongly disagree* might be ranked a score of 1, while *somewhat disagree* is ranked as 2 *slightly disagree* is ranked as 3 *unsure* is ranked as 4, and so on, all the way through to *strongly agree* being ranked as 7.

Additional items around other aspects of the same concept would be included, for example, another 19 items. Then the numeric score of all 20 items would be tallied or otherwise calculated to arrive at an overall composite score on a concept such as “Quantitative Research Efficacy.” Participants could achieve a score that ranges from 20 (if they answered *strongly disagree* to all 20 items) up to and including a score of 140 (if they answered *strongly agree* to all 20 items). This composite score would be a measure of their overall Quantitative Research Efficacy. All the many numeric points along the way are potential values of that variable: 20, 21, 22, 23 . . . 140, meaning it is a continuous variable. There are numerous well-established instruments to measure attributes of people, such as the Beck Depression Inventory (BDI) or the Spielberg State-Trait Anxiety Inventory.

Categorical Variables

Categorical variables, in contrast, are those variables where a participant can only be in one category at any given point in time because each category is mutually exclusive, and the values for that variable cannot be expressed by a continuous range of numbers. For instance, eye color, hair color, and skin color are examples of categorical variables, as are country of residence, postal code, and type of transport vehicle (e.g., car, motorcycle, bicycle, bus, tram, train). A person can only have one eye color or only be in one place or have one type of transport at any given time. Smoker versus non-smoker is a simple example of a categorical variable.

These examples are categorical variables where the categories are inherent, or preexisting, because the concept or variable naturally occurs in discrete, mutually exclusive categories. However, one can also create categorical variables from an existing data set where the data were collected as continuous variables, which is usually the preferred way to do so whenever possible. Continuous variables allow for more rigorous statistical testing to detect relationships between the concepts of interest. For instance, we might be asking in our research whether older people are more likely to have higher scores for depression on the BDI. We could use a statistical analysis program such as SPSS to run a correlation between our continuous variable of age in years and our continuous variable of depression, as measured by the BDI, to answer that research question.

Using Transformed Categorical Variables

Testing for relationships such as the aforementioned example is a category of statistical analysis called

inferential testing, whereby we want to *infer* a relationship between two variables for the population based on the data we collected on our sample and the statistical testing we conducted on that data set. If the relationship is strong enough (termed *statistically significant*) in our sample, we can reasonably infer that it is probably true in the population from which our sample was drawn. For the purposes of inferential statistical testing for relationships between variables, it is always best to collect and use data in the more precise measurement of continuous variables whenever possible to enable the use of more robust and sensitive inferential testing, which will be more likely to detect a statistically significant relationship, if indeed it does exist between the variables.

However, before proceeding with inferential testing, we often want to describe our sample to the audience reading our research report. Descriptive statistics serves that purpose and enables us to summarize the characteristics of our sample in a shorthand way, for succinct reporting in a word-count-limited journal article. So even though we have a single data point about age for all our participants, as a continuous variable, we would like to convert that more precise continuous variable data into less precise categorical variable data, so that we can briefly show the reader the profile of our sample. Combining similar data points into categories is a handy way to accomplish that objective. We would then use SPSS or another statistical analysis package or program to create a new categorical age variable based on the data from our existing continuous variable data. We would direct the program to categorize or *lump together* all the participants’ whose age was, for instance, 0–19 into one category, 20–39 in another, 40–59 in another, 60–74 in another, and so on. We would then assign a label to each category, such as *youth* and *young adult* and *middle-aged adult*, and so on. We could display a bar graph for each age bracket or category and present a very concise visual depiction of the age profile of our sample. Alternatively, we might want to present the data in a table. We might also include in the table the average score on the BDI for each age bracket, to further describe our sample, as part of the descriptive statistical analysis of our data set.

We might even want to use our new categorical age variable to run other different, (although less robust and sensitive) inferential statistical tests. We could ascertain whether the average BDI score is similar in each age bracket, or if one age bracket is statistically significantly different in their levels of depression, from the other age brackets. This inferential testing on the newly created, converted categorical variable now enables us to do group-to-group comparisons of the

various age groups in our sample. For those categorized as smokers, however, we could create another additional variable in our survey and ask how many cigarettes a day they smoke, which would create a continuous variable for that additional concept of their degree or intensity of their smoking behavior. While it may seem efficient to turn a continuous variable into categories (or groups) for the purposes of analyses of variance and other mean comparison analyses, but this almost always loses information and results in less powerful (and less meaningful) analyses. Statisticians prefer to keep their variables continuous and use correlational methods, such as regression, to look for relationships.

CAUSAL-COMPARATIVE DESIGN

A causal-comparative design is a research design that seeks to find relationships between independent and dependent variables after an action or event has already occurred. The researcher's goal is to determine whether the independent variable affected the outcome, or dependent variable, by comparing two or more groups of individuals. There are similarities and differences between causal-comparative research, also referred to as *ex post facto research*, and both correlational and experimental research. This entry discusses these differences, as well as the benefits, process, limitations, and criticism of this type of research design. To demonstrate how to use causal-comparative research, examples in education are presented.

Comparisons With Correlational Research

Many similarities exist between causal-comparative research and correlational research. Both methods are

useful when experimental research has been deemed impossible or unethical as the research design for a particular question. Both causal-comparative and correlational research designs attempt to determine relationships among variables, but neither allows for the actual manipulation of these variables. Thus, neither can definitively state that a true cause-and-effect relationship occurred between these variables. Finally, neither type of design randomly places subjects into control and experimental groups, which limits the generalizability of the results.

Despite similarities, there are distinct differences between causal-comparative and correlational research designs. In causal-comparative research, the researcher investigates the effect of an independent variable on a dependent variable by comparing two or more groups of individuals. For example, an educational researcher may want to determine whether a computer-based ACT program has a positive effect on ACT test scores. In this example, the researcher would compare the ACT scores from a group of students that completed the program with scores from a group that did not complete the program. In correlational research, the researcher works with only one group of individuals. Instead of comparing two groups, the correlational researcher examines the effect of one or more independent variables on the dependent variable within the same group of subjects. Using the same example as above, the correlational researcher would select one group of subjects who have completed the computer-based ACT program. The researcher would use statistical measures to determine whether there was a positive relationship between completion of the ACT program and the students' ACT scores.

Comparisons With Experimental Research

A few aspects of causal-comparative research parallel experimental research designs. Unlike correlational research, both experimental research and causal-comparative research typically compare two or more groups of subjects. Research subjects are generally split into groups on the basis of the independent variable that is the focus of the study. Another similarity is that the goal of both types of research is to determine what effect the independent variable may or may not have on the dependent variable or variables.

While the premises of the two research designs are comparable, there are vast differences between causal-comparative research and experimental research. First and foremost, causal-comparative research occurs after the event or action has been completed. It is a

retrospective way of determining what may have caused something to occur. In true experimental research designs, the researcher manipulates the independent variable in the experimental group. Because the researcher has more control over the variables in an experimental research study, the argument that the independent variable caused the change in the dependent variable is much stronger. Another major distinction between the two types of research is random sampling. In causal-comparative research, the research subjects are already in groups because the action or event has already occurred, whereas subjects in experimental research designs are randomly selected prior to the manipulation of the variables. This allows for wider generalizations to be made from the results of the study.

Table 1 breaks down the causal-comparative, correlational, and experimental methods in reference to whether each investigates cause-effect and whether the variables can be manipulated. In addition, it notes whether groups are randomly assigned and whether the methods study groups or individuals.

When to Use Causal-Comparative Research Designs

Although experimental research results in more compelling arguments for causation, there are many times

when such research cannot, or should not, be conducted. Causal-comparative research provides a viable form of research that can be conducted when other methods will not work. There are particular independent variables that are not capable of being manipulated, including gender, ethnicity, socioeconomic level, education level, and religious preferences. For instance, if researchers intend to examine whether ethnicity affects self-esteem in a rural high school, they cannot manipulate a subject's ethnicity. This independent variable has already been decided, so the researchers must look to another method of determining cause. In this case, the researchers would group students according to their ethnicity and then administer self-esteem assessments. Although the researchers may find that one ethnic group has higher scores than another, they must proceed with caution when interpreting the results. In this example, it might be possible that one ethnic group is also from a higher socioeconomic demographic, which may mean that the socioeconomic variable affected the assessment scores.

Some independent variables should not be manipulated. In educational research, for example, ethical considerations require that the research method not deny potentially useful services to students. For instance, if a guidance counselor wanted to determine whether advanced placement course selection affected college choice, the counselor could not ethically force

Table 1 Comparison of Causal-Comparative, Correlational, and Experimental Research

<i>Method</i>	<i>Investigates Cause–Effect</i>	<i>Manipulates Variable</i>	<i>Randomly Assigns Participants to Groups</i>	<i>Involves Group Comparisons</i>	<i>Studies Groups or Individuals</i>	<i>Focus</i>	<i>Identifies Variables for Experimental Exploration</i>
Causal-comparative research	Yes	No (it already occurred)	No (groups formed prior to study)	Yes	Two or more groups of individuals and one independent variable	Focus on differences of variables between groups	Yes
Correlational research	No	No	No (only one group)	No	Two or more variables and one group of individuals	Focus on relationship among variables	Yes
Experimental research	Yes	Yes	Yes	Yes	Groups or individuals depending on design	Depends on design; focuses on cause/effect of variables	Yes

some students to take certain classes and prevent others from taking the same classes. In this case, the counselor could still compare students who had completed advanced placement courses with those who had not,

but causal conclusions are more difficult than with an experimental design.

Furthermore, causal-comparative research may prove to be the design of choice even when

Figure 1 Flowchart for Conducting a Study

experimental research is possible. Experimental research is both time-consuming and costly. Many school districts do not have the resources to conduct a full-scale experimental research study, so educational leaders may choose to do a causal-comparative study. For example, the leadership might want to determine whether a particular math curriculum would improve math ACT scores more effectively than the curriculum already in place in the school district. Before implementing the new curriculum throughout the district, the school leaders might conduct a causal-comparative study, comparing their district's math ACT scores with those from a school district that has already used the curriculum. In addition, causal-comparative research is often selected as a precursor to experimental research. In the math curriculum example, if the causal-comparative study demonstrates that the curriculum has a positive effect on student math ACT scores, the school leaders may then choose to conduct a full experimental research study by piloting the curriculum in one of the schools in the district.

Conducting Causal Comparative Research

The basic outline for conducting causal-comparative research is similar to that of other research designs. Once the researcher determines the focus of the research and develops hypotheses, he or she selects a sample of participants for both an experimental and a control group. Depending on the type of sample and the research question, the researcher may measure potentially confounding variables to include them in eventual analyses. The next step is to collect data. The researcher then analyzes the data, interprets the results, and reports the findings. Figure 1 illustrates this process.

Determine the Focus of Research

As in other research designs, the first step in conducting a causal-comparative research study is to identify a specific research question and generate a hypothesis. In doing so, the researcher identifies a dependent variable, such as high dropout rates in high schools. The next step is to explore reasons the dependent variable has occurred or is occurring. In this example, several issues may affect dropout rates, including such elements as parental support, socioeconomic level, gender, ethnicity, and teacher support. The researcher will need to select which issue is of importance to his or her research goals. One hypothesis might be, "Students from lower socioeconomic levels drop out of high school at higher rates than students

from higher socioeconomic levels." Thus, the independent variable in this scenario would be socioeconomic levels of high school students.

It is important to remember that many factors affect dropout rates. Controlling for such factors in causal-comparative research is discussed later in this entry. Once the researcher has identified the main research problem, he or she operationally defines the variables. In the above hypothesis, the dependent variable of high school dropout rates is fairly self-explanatory. However, the researcher would need to establish what constitutes lower socioeconomic levels and higher socioeconomic levels. The researcher may also wish to clarify the target population, such as what specific type of high school will be the focus of the study. Using the above example, the final research question might be, "Does socioeconomic status affect dropout rates in the Appalachian rural high schools in East Tennessee?" In this case, causal-comparative would be the most appropriate method of research because the independent variable of socioeconomic status cannot be manipulated.

Because many factors may influence the dependent variable, the researcher should be aware of, and possibly test for, a variety of independent variables. For instance, if the researcher wishes to determine whether socioeconomic level affects a student's decision to drop out of high school, the researcher may also want to test for other potential causes, such as parental support, academic ability, disciplinary issues, and other viable options. If other variables can be ruled out, the case for socioeconomic level's influencing the dropout rate will be much stronger.

Participant Sampling and Threats to Internal Validity

In causal-comparative research, two or more groups of participants are compared. These groups are defined by the different levels of the independent variable(s). In the previous example, the researcher compares a group of high school dropouts with a group of high school students who have not dropped out of school. Although this is not an experimental design, causal-comparative researchers may still randomly select participants within each group. For example, a researcher may select every fifth dropout and every fifth high school student. However, because the participants are not randomly selected and placed into groups, internal validity is threatened. To strengthen the research design and counter threats to internal validity, the researcher might choose to impose the selection techniques of matching, using homogeneous subgroups, or analysis of covariance (ANCOVA), or both.

Matching

One method of strengthening the research sample is to select participants by matching. Using this technique, the researcher identifies one or more characteristics and selects participants who have these characteristics for both the control and the experimental groups. For example, if the researcher wishes to control for gender and grade level, he or she would ensure that both groups matched on these characteristics. If a male 12th-grade student is selected for the experimental group, then a male 12th-grade student must be selected for the control group. In this way the researcher is able to control these two extraneous variables.

Comparing Homogeneous Subgroups

Another control technique used in causal-comparative research is to compare subgroups that are clustered according to a particular variable. For example, the researcher may choose to group and compare students by grade level. He or she would then categorize the sample into subgroups, comparing nine-grade students with other nine-grade students, 10th-grade students with other 10th-grade students, and so forth. Thus, the researcher has controlled the sample for grade level.

Analysis of Covariance

Using the ANCOVA statistical method, the researcher is able to adjust previously disproportionate scores on a pretest in order to equalize the groups on some covariate (control variable). The researcher may want to control for ACT scores and their impact on high school dropout rates. In comparing the groups, if one group's ACT scores are much higher or lower than the other's, the researcher may use the technique of ANCOVA to balance the two groups. This technique is particularly useful when the research design includes a pretest, which assesses the dependent variable before any manipulation or treatment has occurred. For example, to determine the effect of an ACT curriculum on students, a researcher would determine the students' baseline ACT scores. If the control group had scores that were much higher to begin with than the experimental group's scores, the researcher might use the ANCOVA technique to balance the two groups.

Instrumentation and Data Collection

The methods of collecting data for a causal-comparative research study do not differ from any other method of research. Questionnaires, pretests and posttests, various assessments, and behavior observation are common methods for collecting data in any

research study. It is important, however, to also gather as much demographic information as possible, especially if the researcher is planning to use the control method of matching.

Data Analysis and Interpretation

Once the data have been collected, the researcher analyzes and interprets the results. Although causal-comparative research is not true experimental research, there are many methods of analyzing the resulting data, depending on the research design. It is important to remember that no matter what methods are used, causal-comparative research does not definitively prove cause-and-effect results. Nevertheless, the results will provide insights into causal relationships between the variables.

Inferential Statistics

When using inferential statistics in causal-comparative research, the researcher hopes to demonstrate that a relationship exists between the independent and dependent variables. Again, the appropriate method of analyzing data using this type of statistics is determined by the design of the research study. The three most commonly used methods for causal-comparative research are the chi-square test, paired-samples and independent t tests, and analysis of variance (ANOVA) or ANCOVA.

Pearson's chi-square, the most commonly used chi-square test, allows the researcher to determine whether there is a statistically significant relationship between the experimental and control groups based on frequency counts. This test is useful when the researcher is working with nominal data, that is, different categories of treatment or participant characteristics, such as gender. For example, if a researcher wants to determine whether males and females learn more efficiently from different teaching styles, the researcher may compare a group of male students with a group of female students. Both groups may be asked whether they learn better from audiovisual aids, group discussion, or lecture. The researcher could use chi-square testing to analyze the data for evidence of a relationship.

Another method of testing relationships in causal-comparative research is to use independent or dependent t tests. When the researcher is comparing the mean scores of two groups, these tests can determine whether there is a significant difference between the control and experimental groups. The independent t test is used in research designs when no controls have been applied to the samples, while the dependent t test is appropriate for designs in which matching has been applied to the samples. One example of the use of t testing in causal-comparative research is to determine the significant

difference in math course grades between two groups of elementary school students when one group has completed a math tutoring course. If the two samples were matched on certain variables such as gender and parental support, the dependent t test would be used. If no matching was involved, the independent t test would be the test of choice. The results of the t test allow the researcher to determine whether there is a statistically significant relationship between the independent variable of the math tutoring course and the dependent variable of math course grade.

To test for relationships between three or more groups and a continuous dependent variable, a researcher might select the statistical technique of one-way ANOVA. Like the independent t test, this test determines whether there is a significant difference between groups based on their mean scores. In the example of the math tutoring course, the researcher may want to determine the effects of the course for students who attended daily sessions and students who attended weekly sessions, while also assessing students who never attended sessions. The researcher could compare the average math grades of the three groups to determine whether the tutoring course had a significant impact on the students' overall math grades.

Limitations

Although causal-comparative research is effective in establishing relationships between variables, there are many limitations to this type of research. Because causal-comparative research occurs *ex post facto*, the researcher has no control over the variables and thus cannot manipulate them. In addition, there are often variables other than the independent variable(s) that may impact the dependent variable(s). Thus, the researcher cannot be certain that the independent variable caused the changes in the dependent variable. In order to counter this issue, the researcher must test several different theories to establish whether other variables affect the dependent variable. The researcher can reinforce the research hypothesis if he or she can demonstrate that other variables do not have a significant impact on the dependent variable.

Reversal causation is another issue that may arise in causal-comparative research. This problem occurs when it is not clear that the independent variable caused the changes in the dependent variable, or that a dependent variable caused the independent variable to occur. For example, if a researcher hoped to determine the success rate of an advanced English program on students' grades, he or she would have to determine whether the English program had a positive effect on the students, or in the case of reversal causation, whether students

who make higher grades do better in the English program. In this scenario, the researcher could establish which event occurred first. If the students had lower grades before taking the course, then the argument that the course impacted the grades would be stronger.

The inability to construct random samples is another limitation in causal-comparative research. There is no opportunity to randomly choose participants for the experimental and control groups because the events or actions have already occurred. Without random assignment, the results cannot be generalized to the public, and thus the researcher's results are limited to the population that has been included in the research study. Despite this problem, researchers may strengthen their argument by randomly selecting participants from the previously established groups. For example, if there were 100 students who had completed a computer-based learning course, the researcher would randomly choose 20 students to compare with 20 randomly chosen students who had not completed the course. Another method of reinforcing the study would be to test the hypothesis with several different population samples. If the results are the same in all or most of the sample, the argument will be more convincing.

Criticisms

There have been many criticisms of causal-comparative research. For the most part, critics reject the idea that causal-comparative research results should be interpreted as evidence of causal relationships. These critics believe that there are too many limitations in this type of research to allow for a suggestion of cause and effect. Some critics are frustrated with researchers who hold that causal-comparative research provides stronger causal evidence than correlational research does. Instead, they maintain that neither type of research can produce evidence of a causal relationship, so neither is better than the other. Most of these critics argue that experimental research designs are the only method of research that can illustrate any type of causal relationships between variables. Almost all agree, however, that experimental designs potentially provide the strongest evidence for causation.

CAUSE AND EFFECT

Cause and effect refers to a relationship between two phenomena in which one phenomenon is the reason behind the other. For example, eating too much fast food without any physical activity leads to weight gain. Here eating without any physical activity is the “cause” and weight gain is the “effect.” Another popular example in the discussion of cause and effect is that of smoking and lung cancer. A question that has surfaced in cancer research in the past several decades is, What is the effect of smoking on an individual’s health? Also asked is the question, Does smoking cause lung cancer? Using data from observational studies, researchers have long established the relationship between smoking and the incidence of lung cancer; however, it took compelling evidence from several studies over several decades to establish smoking as a “cause” of lung cancer.

The term *effect* has been used frequently in scientific research. Most of the time, it can be seen that a statistically significant result from a linear regression or correlation analysis between two variables X and Y is explained as effect. Does X really cause Y or just relate to Y ? The association (correlation) of two variables with each other in the statistical sense does not imply that one is the cause and the other is the effect. There needs to be a mechanism that explains the relationship in order for the association to be a causal one. For example, without the discovery of the substance nicotine in tobacco, it would have been difficult to establish the causal relationship between smoking and lung cancer. Tobacco companies have claimed that since there is not a single randomized controlled trial that establishes the differences in death from lung cancer between smokers and nonsmokers, there was no causal relationship. However, a cause-and-effect relationship is established by observing the same phenomenon in a wide variety of settings while controlling for other suspected mechanisms.

Statistical correlation (e.g., association) describes how the values of variable Y of a specific population are associated with the values of another variable X from the same population. For example, the death rate from lung cancer increases with increased age in the general population. The association or correlation describes the situation that there is a relationship between age and the death rate from lung cancer. *Randomized prospective studies* are often used as a tool to establish a causal effect. Time is a key element in causality because the cause must happen prior to the effect. Causes are often referred to as *treatments* or *exposures* in a study. Suppose a causal relationship between an investigational drug A and response Y needs to be established. Suppose Y_A represents the response when the participant is treated using A and Y_0 is the response when the subject is treated with placebo under the same conditions. The causal effect of the investigational drug is defined as the population average $\delta = E(Y_A - Y_0)$. However, a person cannot be treated with both placebo and Treatment A under the same conditions. Each participant in a randomized study will have, usually, equal potential of receiving Treatment A or the placebo. The responses from the treatment group and the placebo group are collected at a specific time after exposure to the treatment or placebo. Since participants are randomized to the two groups, it is expected that the conditions (represented by covariates) are balanced between the two groups. Therefore, randomization controls for other possible causes that can affect the response Y , and hence the difference between the average responses from the two groups, can be thought of an estimated causal effect of treatment A on Y .

Even though a randomized experiment is a powerful tool for establishing a causal relationship, a randomization study usually needs a lot of resources and time, and sometimes it cannot be implemented for ethical or practical reasons. Alternatively, an *observational study* may be a good tool for causal inference. In an observational study, the probability of receiving (or not receiving) treatment is assessed and accounted for. In the example of the effect of smoking on lung cancer, smoking and not smoking are the treatments. However, for ethical reasons, it is not practical to randomize subjects to treatments. Therefore, researchers had to rely on observational studies to establish the causal effect of smoking on lung cancer.

Causal inference plays a significant role in medicine, epidemiology, and social science. An issue about the average treatment effect is also worth mentioning. The average treatment effect, $\delta = E(Y_1) - E(Y_2)$, between two treatments is defined as the difference between two outcomes, but, as mentioned previously, a subject can receive only one of “rival” treatments. In other words,

it is impossible for a subject to have two outcomes at the same time. Y_1 and Y_2 are called *counterfactual outcomes*. Therefore, the average treatment effect can never be observed. In the causal inference literature, several estimating methods of average treatment effect are proposed to deal with this obstacle. Also, for observational study, estimators for average treatment effect with confounders controlled have been proposed.

CEILING EFFECT

The term *ceiling effect* is a measurement limitation that occurs when the highest possible score or close to the highest score on a test or measurement instrument is reached, thereby decreasing the likelihood that the testing instrument has accurately measured the intended domain. A ceiling effect can occur with questionnaires, standardized tests, or other measurements used in research studies. A person's reaching the ceiling or scoring positively on all or nearly all the items on a measurement instrument leaves few items to indicate whether the person's true level of functioning has been accurately measured. Therefore, whether a large percentage of individuals reach the ceiling on an instrument or whether an individual scores very high on an instrument, the researcher or interpreter has to consider that what has been measured may be more of a reflection of the parameters of what the instrument is able to measure than of how the individuals may be ultimately functioning. In addition, when the upper limits of a measure are reached, discriminating between the functioning of individuals within the upper range is difficult. This entry focuses on the impact of ceiling effects on the interpretation of research results, especially the results of standardized tests.

Interpretation of Research Results

When a ceiling effect occurs, the interpretation of the results attained is impacted. For example, a health

survey may include a range of questions that focus on the low to moderate end of physical functioning (e.g., individual is able to walk up a flight of stairs without difficulty) versus a range of questions that focus on higher levels of physical functioning (e.g., individual is able to walk at a brisk pace for 1 mile without difficulty). Questions within the range of low to moderate physical functioning provide valid items for individuals on that end of the physical functioning spectrum rather than for those on the higher end of the physical functioning spectrum. Therefore, if an instrument geared toward low to moderate physical functioning is administered to individuals with physical health on the upper end of the spectrum, a ceiling effect will likely be reached in a large portion of the cases, and interpretation of their ultimate physical functioning would be limited.

A ceiling effect can be present within results of a research study. For example, a researcher may administer the health survey described in the previous paragraph to a treatment group in order to measure the impact of a treatment on overall physical health. If the treatment group represents the general population, the results may show a large portion of the treatment group to have benefited from the treatment because they have scored high on the measure. However, this high score may signify the presence of a ceiling effect, which calls for caution when one is interpreting the significance of the positive results. If a ceiling effect is suspected, an alternative would be to use another measure that provides items that target better physical functioning. This would allow participants to demonstrate a larger degree of differentiation in physical functioning and provide a measure that is more sensitive to change or growth from the treatment.

Standardized Tests

The impact of the ceiling effect is important when interpreting standardized test results. Standardized tests have higher rates of score reliability because the tests have been administered to a large sampling of the population. The large sampling provides a scale of standard scores that reliably and validly indicates how close a person who takes the same test performs compared with the mean performance on the original sampling. Standardized tests include aptitude tests such as the Wechsler Intelligence Scales, the Stanford-Binet Scales, and the Scholastic Aptitude Test, and achievement tests such as the Iowa Test of Basic Skills and the Woodcock-Johnson: Tests of Achievement.

When individuals score at the upper end of a standardized test, especially 3 standard deviations from the mean, then the ceiling effect is a factor. It is reasonable

to conclude that such a person has exceptional abilities compared with the average person within the sampled population, but the high score is not necessarily a highly reliable measure of the person's true ability. What may have been measured is more a reflection of the test than of the person's true ability. In order to attain an indication of the person's true ability when the ceiling has been reached, an additional measure with an increased range of difficult items would be appropriate to administer. If such a test is not available, the test performance would be interpreted stating these limitations.

The ceiling effect should also be considered when one is administering a standardized test to an individual who is at the top end of the age range for a test and who has elevated skills. In this situation, the likelihood of a ceiling effect is high. Therefore, if a test administrator is able to use a test that places the individual on the lower age end of a similar or companion test, the chance of a ceiling effect would most likely be eliminated. For example, the Wechsler Intelligence Scales have separate measures to allow for measurement of young children, children and adolescents, and older adolescents and adults. The upper end and lower end of the measures overlap, meaning that a 6- to 7-year-old could be administered the Wechsler Preschool and Primary Scale of Intelligence or the Wechsler Intelligence Scale for Children. In the event a 6-year-old is cognitively advanced, the Wechsler Intelligence Scale for Children would be a better choice in order to avoid a ceiling effect.

It is important for test developers to monitor ceiling effects on standardized instruments as they are utilized in the public. If a ceiling effect is noticed within areas of a test over time, those elements of the measure should be improved to provide better discrimination for high performers. The rate of individuals scoring at the upper end of a measure should coincide with the standard scores and percentiles on the normal curve.

CENTRAL LIMIT THEOREM

The central limit theorem (CLT) is, along with the theorems known as *laws of large numbers*, the cornerstone of *probability theory*. In simple terms, the theorem describes the distribution of the sum of a large number of random numbers, all drawn independently from the same probability distribution. It predicts that, regardless of this distribution, as long as it has finite variance, then the sum follows a precise law, or distribution, known as the *normal distribution*.

Let us describe the normal distribution with mean μ and variance σ^2 : It is defined through its density function,

$$f(x) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-(x-\mu)^2/2\sigma^2},$$

where the variable x ranges from $-\infty$ to $+\infty$. This means that if a random variable follows this distribution, then the probability that it is larger than a and smaller than b is equal to the integral of the function $f(x)$ (the area under the graph of the function) from $x = a$ to $x = b$. The normal density is also known as Gaussian density, named for Carl Friedrich Gauss, who used this function to describe astronomical data. If we put $\mu = 0$ and $\sigma^2 = 1$ in the above formula, then we obtain the so-called *standard normal density*.

In precise mathematical language, the CLT states the following: Suppose that $X_1, X_2, \dots$ are independent random variables with the same distribution, having mean μ and variance σ^2 but being otherwise arbitrary. Let $S_n = X_1 + \dots + X_n$ be their sum. Then

$$P\left(a < \frac{S_n - n\mu}{\sqrt{n\sigma^2}} < b\right) \rightarrow \int_a^b \frac{1}{\sqrt{2\pi}} e^{-t^2/2} dt,$$

as $n \rightarrow \infty$.

It is more appropriate to define the standard normal density as the density of a random variable ζ with zero

mean and variance 1 with the property that, for every a and b there is c such that if ζ_1, ζ_2 are independent copies of ζ , then $a\zeta_1 + b\zeta_2$ is a copy of $c\zeta$. It follows that $a^2 + b^2 = c^2$ holds and that there is only one choice for the density of ζ , namely, the standard normal density.

As an example, consider tossing a fair coin $n = 1,000$ times and determining the probability that fewer than 450 heads are obtained. The CLT can be used to give a good approximation of this probability. Indeed, if we let X_i be a random variable that takes value 1 if heads show up at the i th toss or value 0 if tails show up, then we see that the assumptions of the CLT are satisfied because the random variables have the same mean $\mu = 1/2$ and variance $\sigma^2 = 1/4$. On the other hand, $S_n = X_1 + \cdots + X_n$ is the number of heads. Since $S_n \leq 450$ if and only if $(S_n - n\mu) / \sqrt{n\sigma^2} \leq (450 - 500) / \sqrt{250} = -3.162$, we find, by the CLT, that the probability that we get at most 450 heads equals the integral of the standard density from $-\infty$ to -3.162 . This integral can be computed with the help of a computer (or tables in olden times) and found to be about 0.00078, which is a reasonable approximation. Incidentally, this kind of thing leads to the so-called *statistical hypothesis testing*: If we toss a coin and see 430 heads and 570 tails, then we should be suspicious that the coin is not fair.

Origins

The origins of the CLT can be traced to a paper by Abraham de Moivre (1733), who described the CLT for symmetric Bernoulli trials; that is, in tossing a fair coin n times, the number S_n of heads has a distribution that is approximately that of $\frac{n}{2} + \frac{\sqrt{n}}{2}\zeta$. The result fell into obscurity but was revived in 1812 by Pierre-Simon Laplace, who proved and generalized de Moivre's result to asymmetric Bernoulli trials (weighted coins). Nowadays, this particular case is known as the *de Moivre-Laplace CLT* and is usually proved using *Stirling's approximation* for the product $n!$ of the first n positive integers: $n! \approx n^n e^{-n} \sqrt{2\pi n}$. The factor $\sqrt{2\pi}$ here is the same as the one appearing in the normal density. Two 19th-century Russian mathematicians, Pafnuty Chebyshev and A. A. Markov, generalized the CLT of their French predecessors and proved it using the *method of moments*.

The Modern CLT

The modern formulation of the CLT gets rid of the assumption that the summands be identically distributed random variables. Its most general and useful

form is that of the Finnish mathematician J. W. Lindeberg (1922). It is stated for *triangular arrays*, that is, random variables $S_n = X_{n,1}, X_{n,2}, \dots, X_{n,k_n}$, depending on two indices that, for fixed n , are independent with respect to the second index. Letting $S_n = X_1 + \cdots + X_{n,k_n}$ be the sum with respect to the second index, we have that S_n minus its mean, ES_n , and divided by its standard deviation, has a distribution that, as n tends to ∞ , is standard normal, provided an asymptotic negligibility condition for the variances holds. A version of Lindeberg's theorem was formulated by A. Liapounoff in 1901. It is worth pointing out that Liapounoff introduced a new proof technique based on *characteristic functions* (also known as *Fourier transforms*), whereas Lindeberg's technique was an ingenious step-by-step replacement of the general summands by normal ones. Liapounoff's theorem has a condition that is weaker than that of Lindeberg but is quite good in practice. In 1935, Paul Lévy and William Feller established necessary conditions for the validity of the CLT. In 1951, H. F. Trotter gave an elementary analytical proof of the CLT.

The Functional CLT

The functional CLT is stated for summands that take values in a multidimensional (one talks of random vectors in a Euclidean space) or even infinite-dimensional space. A very important instance of the functional CLT concerns convergence to *Brownian motion*, which also provides a means of defining this most fundamental object of modern probability theory. Suppose that S_n is as stated in the beginning of this entry. Define a function $s_n(t)$ of "time" as follows: At time $t = k/n$, where k is a positive integer, let $s_n(t)$ have value $(S_k - \mu k) / \sigma\sqrt{n}$; now join the points $[k/n, s_n(k/n)], [(k+1)/n, s_n(k+1)/n]$ by a straight line segment, for each value of k , to obtain the graph of a continuous random function $s_n(t)$. *Donsker's theorem* states that the probability distribution of the random function $s_n(t)$ converges (in a certain sense) to the distribution of a random function, or stochastic process, which can be defined to be the standard Brownian motion.

Other Versions and Consequences of the CLT

Versions of the CLT for *dependent random variables* also exist and are very useful in practice when independence is either violated or not possible to establish. Such versions exist for Markov processes, for regenerative processes, and for martingales, as well as others.

The work on the CLT gave rise to the general area known as *weak convergence (of stochastic processes)*, the origin of which is in Yuri Prokhorov (1956) and Lucien Le Cam (1957). Nowadays, every result of CLT can (and should) be seen in the light of this general theory.

Finally, it should be mentioned that all flavors of the CLT rely heavily on the assumption that the probability that the summands be very large is small, which is often cast in terms of finiteness of a moment such as the variance. In a variety of applications, *heavy-tailed random variables* do not satisfy this assumption. The study of limit theorems of sums of independent heavy-tailed random variables leads to the so-called *stable distributions*, which are generalizations of the normal law, and like the normal law, they are “preserved by linear transformations,” but they all have infinite variance. Boris Gnedenko and A. N. Kolmogorov call such limit results central limit theorems as well, but the terminology is not well established, even though the research, applications, and use of such results are quite extended nowadays. A functional CLT (an analog of Donsker’s theorem) for sums of heavy-tailed random variables gives rise to the so-called *stable processes*, which are special cases of processes with stationary and independent increments known as *Lévy processes*.

Uses of the CLT

The uses of the CLT are numerous. First, it is a cornerstone of *statistics*. Indeed, one could argue that without the CLT, there would be no such subject; for example, confidence intervals and parameter and density estimation make explicit use of the CLT or a version of it known as the *local limit theorem*, which, roughly speaking, states that the probability density function of S_n converges to the normal density. Of particular importance are dependent versions of the CLT, which find applications in the modern areas of data mining and artificial intelligence.

In connection with statistics, of importance is the question of speed of convergence to CLT. Answers to this are given by the classical Berry-Esséen theorem or by more modern methods consisting of embedding the random sums into a Brownian motion (via the so-called Hungarian construction of Komlós, Major, and Tusnády).

In *applied probability*, various stochastic models depending on normal random variables or Brownian motions can be justified via (functional) central limit theorems. Areas within applied probability benefiting

from the use of the CLT are, among others, stochastic networks, particle systems, stochastic geometry, the theory of risk, mathematical finance, and stochastic simulation.

There are also various applications of the CLT in engineering, physics (especially in statistical mechanics), and mathematical biology.

Example 1: Confidence Intervals.

Suppose we set up an experiment in which we try to find out how the glucose blood level in a certain population affects a disease. We introduce a mathematical model as follows: Assume that the glucose level data we collect are observations of independent random variables, each following a probability distribution with an unknown mean θ (the “true” glucose level) and wish to estimate this θ . Letting $X_1, \dots, X_n$ be the data we have, a reasonable estimate for θ is the sample mean $\bar{X} = S_n / n = (X_1 + \dots + X_n) / n$. A p -confidence interval (where p is a large probability, say $p = .95$) is an interval such that the probability that it contains $\bar{X}$ is at least p . To find this confidence interval, we use the central limit theorem to justify that $n(\bar{X} - \frac{\sigma}{\sqrt{n}}) = (S_n - n\theta) / \sigma\sqrt{n}$ is approximately standard normal. We then find the number α such that $P(-\alpha < \zeta < \alpha) = p$, where ζ is a standard normal random variable, and, on replacing ζ by $n(\bar{X} - \frac{\sigma}{\sqrt{n}})$, we have that $P(\bar{X} - \alpha\sigma\sqrt{n} < \theta < \bar{X} + \alpha\sigma\sqrt{n}) = p$, meaning that the interval centered at $\bar{X}$ and having width $2\alpha\sigma\sqrt{n}$ is a p -confidence interval. One way to deal with the fact that σ may be unknown is to replace it by the sample standard deviation.

Example 2: An Invariance Principle

A very important, for applications, consequence of the CLT (or, more generally, of the principle of weak convergence mentioned above) is that it yields information about functions of the approximating sequence. For example, consider a fair game of chance, say tossing a fair coin whereby 1 is won on appearance of heads or lost on appearance of tails. Let S_n be the net winnings in n coin tosses (negative if there is a net loss). Define the quantity T_n roughly as the number of times before n that the gambler had a net loss. By observing that this quantity is a function of the function $s_n(t)$ discussed earlier, and using the Donsker’s CLT, it can be seen that the distribution function of T_n / n has,

approximately, the arcsine law: $P(T_n / n \leq x) \approx (2 / \pi) \arcsin \sqrt{x}$, for large n .

CENTRAL TENDENCY, MEASURES OF

One of the most common statistical analyses used in descriptive statistics is a process to determine where the average of a set of values falls. There are multiple ways to determine the middle of a group of numbers, and the method used to find the average will determine what information is known and how that average should be interpreted. Depending on the data one has, some methods for finding the average may be more appropriate than others.

The *average* describes the typical or most common number in a group of numbers. It is the one value that best represents the entire group of values. Averages are used in most statistical analyses and even in everyday life. If one wanted to find the typical house price, family size, or score on a test, some form of average would be computed each time. In fact, one would compute a different type of average for each of those three examples.

Researchers use different ways to calculate the average, based on the types of numbers they are examining. Some numbers, measured on the nominal level of measurement, are not appropriate to do some types of averaging. For example, if one were examining the variable of types of vegetables, and the labels of the levels were cucumbers, zucchini, carrots, and turnips, if one performed some types of average, one may find that the average vegetable was 3/4 carrot and 1/4 turnip, which makes no sense at all. Similarly, using some types of average on interval-level continuous variables may result in an average that is very imprecise and not very representative of the sample one is using. When the three main methods for examining the average are collectively discussed, they are referred to as *measures of central tendency*. The three primary measures of central tendency commonly used by researchers are the *mean*, the *median*, and the *mode*.

Mean

The mean is the most commonly used (and misused) measure of central tendency. The mean is defined as the sum of all the scores in the sample, divided by the

number of scores in the sample. This type of mean is also referred to as *the arithmetic mean*, to distinguish it from other types of means, such as the geometric mean or the harmonic mean. Several common symbols or statistical notations are used to represent the mean, including $\bar{x}$, which is read as *x-bar* (the mean of the sample), and μ which is read as *mu* (the mean of the population). Some research articles also use an italicized uppercase letter *M* to indicate the sample mean.

Much as different symbols are used to represent the mean, different formulas are used to calculate the mean. The difference between the two most common formulas is found only in the symbols used, as the formula for calculating the mean of a sample uses the symbols appropriate for a sample, and the other formula is used to calculate the mean of a population and as such uses the symbols that refer to a population.

For calculating the mean of a sample, use

$$\bar{x} = \Sigma x / n.$$

For calculating the mean of a population, use

$$\mu = \Sigma X / N.$$

Calculating the mean is a very simple process. For example, if a student had turned in five homework assignments that were worth 10 points each, the student's scores on those assignments might have been 10, 8, 5, 7, and 9. To calculate the student's mean score on the homework assignments, first one would add the values of all the homework assignments:

$$10 + 8 + 5 + 7 + 9 = 39.$$

Then one would divide the sum by the total number of assignments (which was 5):

$$39 / 5 = 7.8.$$

For this example, 7.8 would be the student's mean score for the five homework assignments. That indicates that, on average, the student scored a 7.8 on each homework assignment.

Other Definitions

Other definitions and explanations can also be used when interpreting the mean. One common description is that the mean is like a balance point. The mean is located at the center of the values of the sample or population. If one were to line up the values of each score on a number line, the mean would fall at the exact point where the values are equal on each side; the mean is the point closest to the squared distances of all the scores in the distribution.

Another way of thinking about the mean is as the amount per individual, or how much each individual would receive if one were to divide the total amount equally. If Steve has a total of \$50, and if he were to divide it equally among his four friends, each friend would receive $50 / 4 = \$12.50$. Therefore, \$12.50 would be the mean.

The mean has several important properties that are found only with this measure of central tendency. If one were to change a score in the sample from one value to another value, the calculated value of the mean would change. The value of the mean would change because the value of the sum of all the scores would change, thus changing the numerator. For example, given the scores in the earlier homework assignment example (10, 8, 5, 7, and 9), the student previously scored a mean of 7.8. However, if one were to change the value of the score of 9 to a 4 instead, the value of the mean would change:

$$\begin{aligned} 10 + 8 + 5 + 7 + 4 &= 34 \\ 34 / 5 &= 6.8 \end{aligned}$$

By changing the value of one number in the sample, the value of the mean was lowered by one point. Any change in the value of a score will result in a change in the value of the mean.

If one were to remove or add a number to the sample, the value of the mean would also change, as then there would be fewer (or greater) numbers in the sample, thus changing the numerator and the denominator. For example, if one were to calculate the mean of only the first four homework assignments (thereby removing a number from the sample),

$$\begin{aligned} 10 + 8 + 5 + 7 &= 30 \\ 30 / 4 &= 7.5. \end{aligned}$$

If one were to include a sixth homework assignment (adding a number to the sample) on which the student scored an 8,

$$\begin{aligned} 10 + 8 + 5 + 7 + 9 + 8 &= 47 \\ 47 / 6 &= 7.83. \end{aligned}$$

Either way, whether one adds or removes a number from the sample, the mean will almost always change in value. The only instance in which the mean will not change is if the number that is added or removed is exactly equal to the mean. For example, if the score on the sixth homework assignment had been 7.8,

$$\begin{aligned} 10 + 8 + 5 + 7 + 9 + 7.8 &= 46.8 \\ 46.8 / 6 &= 7.8. \end{aligned}$$

If one were to add (or subtract) a constant to each score in the sample, the mean will increase (or decrease) by the same constant value. So if the professor added three points to the score on every homework assignment,

$$\begin{aligned}(10 + 3) + (8 + 3) + (5 + 3) + (7 + 3) + (9 + 3) \\ 13 + 11 + 8 + 10 + 12 = 54 \\ 54 / 5 = 10.8.\end{aligned}$$

The mean homework assignment score increased by three points. Similarly, if the professor took away two points from each original homework assignment score,

$$\begin{aligned}(10 - 2) + (8 - 2) + (5 - 2) + (7 - 2) + (9 - 2) \\ 8 + 6 + 3 + 5 + 7 = 29 \\ 29 / 5 = 5.8.\end{aligned}$$

The mean homework assignment score decreased by two points. The same type of situation will occur with multiplication and division. If one multiplies (or divides) every score by the same number, the mean will also be multiplied (or divided) by that number. Multiplying the five original homework scores by four

$$\begin{aligned}10(4) + 8(4) + 5(4) + 7(4) + 9(4) \\ 40 + 32 + 20 + 28 + 36 = 156 \\ 156 / 5 = 31.2\end{aligned}$$

results in the mean being multiplied by 4 as well. Dividing each score by 3,

$$\begin{aligned}10 / 3 + 8 / 3 + 5 / 3 + 7 / 3 + 9 / 3 \\ 3.33 + 2.67 + 1.67 + 2.33 + 3 = 13 \\ 13 / 5 = 2.6\end{aligned}$$

will result in the mean being divided by 3 as well. Weighted mean = $(\Sigma x_1 + \Sigma x_2 + \dots \Sigma x_n) / (n_1 + n_2 + \dots n_n)$.

To calculate the weighted mean, one will divide the sum of all the scores in every group by the number of scores in every group. For example, if Carla taught three classes, and she gave each class a test, the first class of 25 students might have a mean of 75, the second class of 20 students might have a mean of 85, and the third class of 30 students might have a mean of 70. To calculate the weighted mean, Carla would first calculate the summed scores for each class, then add the summed scores together, then divide by the total number of students in all three classes. To find the summed scores, Carla will need to rework the formula for the sample mean to find the summed scores instead:

$$\bar{X} = \Sigma X / n \text{ becomes } \Sigma x = \bar{x}(n).$$

With this reworked formula, find each summed score first:

$$\begin{aligned}\Sigma x_1 &= 75(25) = 1,875 \\ \Sigma x_2 &= 85(20) = 1,700 \\ \Sigma x_3 &= 70(30) = 2,100.\end{aligned}$$

Next, add the summed scores together:

$$1,875 + 1,700 + 2,100 = 5,675.$$

Then add the number of students per class together:

$$25 + 20 + 30 = 75.$$

Finally, divide the total summed scores by the total number of students:

$$5,675 / 75 = 75.67$$

This is the weighted mean for the test scores of the three classes taught by Carla.

Median

The median is the second measure of central tendency. It is defined as the score that cuts the distribution exactly in half. Much as the mean can be described as the balance point where the values on each side are identical, and the median is the point where the number of scores on each side is equal. As such, the median is influenced more by the number of scores in the distribution than by the values of the scores in the distribution. The median is also the same as the 50th percentile of any distribution. Generally, the median is not abbreviated or symbolized, but occasionally *Mdn* is used.

The median is simple to identify. The method used to calculate the median is the same for both samples and populations. It requires only two steps to calculate the median. In the first step, order the numbers in the sample from lowest to highest. So if one were to use the homework scores from the mean example, 10, 8, 5, 7, and 9, one would first order them 5, 7, 8, 9, and 10. In the second step, find the middle score. In this case, there is an odd number of scores, and the score in the middle is 8.

$$5 \ 7 \ 8 \ 9 \ 10$$

Notice that the median that was calculated is not the same as the mean for the same sample of homework assignments. This is because of the different ways in which those two measures of central tendency are calculated.

It is simple to find the middle when there are an odd number of scores, but it is a bit more complex when the sample has an even number of scores. For example, when there were six homework scores (10, 8, 5, 7, 9,

and 8), one would still line up the homework scores from lowest to highest, then find the middle:

5 7 8 | 8 9 10.

In this example, the median falls between two identical scores, so one can still say that the median is 8. If the two middle numbers were different, one would find the middle number between the two numbers. For example, if one increased one of the student's homework scores from an 8 to a 9,

5 7 8 | 9 9 10.

In this case, the middle falls halfway between 8 and 9 at a score of 8.5.

Statisticians disagree over the correct method for calculating the median when the distribution has multiple repeated scores in the center of the distribution. Some statisticians use the methods described above to find the median, whereas others believe the scores in the middle need to be reduced to fractions to find the exact midpoint of the distribution. So in a distribution with the following scores,

2 3 3 4 5 5 5 5 6,

some statisticians would say the median is 5, whereas others (using the fraction method) would report the median as 4.7.

Mode

The mode is the last measure of central tendency. It is the value that occurs most frequently. It is the simplest and least precise measure of central tendency. Generally, in writing about the mode, scholars label it simply *mode*, although some books or papers use *Mo* as an abbreviation. The method for finding the mode is the same for both samples and populations. Although there are several ways one could find the mode, a simple method is to list each score that appears in the sample. The score that appears the most often is the mode. For example, given the following sample of numbers,

3, 4, 6, 2, 7, 4, 5, 3, 4, 7, 4, 2, 6, 4, 3, 5,

one could arrange them in numerical order:

2, 2, 3, 3, 3, 4, 4, 4, 4, 4, 5, 5, 6, 6, 7, 7.

Once the numbers are arranged, it becomes apparent that the most frequently appearing number is 4:

2, 2, 3, 3, 3, 4, 4, 4, 4, 4, 5, 5, 6, 6, 7, 7.

Thus 4 is the mode of that sample of numbers. Unlike the mean and the median, it is possible to have

more than one mode. If one were to add two threes to the sample,

2, 2, 3, 3, 3, 3, 3, 4, 4, 4, 4, 4, 5, 5, 6, 6, 7, 7.

then both 3 and 4 would be the most commonly occurring number, and the mode of the sample would be 3 and 4. The term used to describe a sample with two modes is *bimodal*. If there are more than two modes in a sample, one says the sample is *multimodal*.

When to Use Each Measure

Because each measure of central tendency is calculated with a different method, each measure is different in its precision of measuring the middle as well as which numbers it is best suited for. One basic recommendation for choosing the correct measure of central tendency is to be consistent with the level of measurement used in operationalizing the variable. This approach suggests that the mode should be used for nominal (or categorical) levels of measurement, the median should be used for ordinal level measurement, and the mean should be used for interval and ratio levels of measurement.

Mean

The mean is often used as the default measure of central tendency. As most people understand the concept of average, they tend to use the mean whenever a measure of central tendency is needed, including times when it is not appropriate to use the mean. Many statisticians would argue that the mean should not be calculated for numbers that are measured at the nominal or ordinal levels of measurement, due to difficulty in the interpretation of the results. The mean is also used in other statistical analyses, such as calculations of standard deviation. If the numbers in the sample are fairly normally distributed, and there is no specific reason that one would want to use a different measure of central tendency, then the mean should be the best measure to use.

Median

There are several reasons to use the median instead of the mean. Many statisticians believe that it is inappropriate to use the mean to measure central tendency if the distribution was measured at the ordinal level. Because variables measured at the ordinal level contain information about direction but not distance, and because the mean is measured in terms of distance, using the mean to calculate central tendency would provide information that is difficult to interpret.

Another occasion to use the median is when the distribution contains an *outlier*. An outlier is a value that is very different from the other values. Outliers tend to be located at the far extreme of the distribution, either high or low. As the mean is so sensitive to the value of the scores, using the mean as a measure of central tendency in a distribution with an outlier would result in a nonrepresentative score. For example, looking again at the five homework assignment scores, if one were to replace the nine with a score of 30,

$$\begin{aligned} 5 \ 7 \ 8 \ 9 \ 10 &\text{ becomes } 5 \ 7 \ 8 \ 30 \ 10 \\ 5 + 7 + 8 + 30 + 10 &= 60 \\ 60 / 5 &= 12. \end{aligned}$$

By replacing just one value with an outlier, the newly calculated mean is not a good representation of the average values of our distribution. The same would occur if one replaced the score of 9 with a very low number:

$$\begin{aligned} 5 \ 7 \ 8 \ 9 \ 10 &\text{ becomes } 5 \ 7 \ 8 \ -4 \ 10 \\ 5 + 7 + 8 + -4 + 10 &= 26 \\ 26 / 5 &= 5.2. \end{aligned}$$

Since the mean is so sensitive to outliers, it is best to use the median for calculating central tendency. Examining the previous example, but using the median,

$$\begin{aligned} 5 \ 7 \ 8 \ -4 \ 10 \\ -4 \ 5 \ 7 \ 8 \ 10. \end{aligned}$$

The middle number is 7; therefore, the median is 7, a much more representative number than the mean of that sample, 5.2.

If the numbers in the distribution were measured on an item that had an open-ended option, one should use the median as the measure of central tendency. For example, a question that asks for demographic information such as age or salary may include either a lower or upper category that is open ended:

<i>Number of cars owned</i>	<i>Frequency</i>
0	4
1	10
2	16
3 or more	3

The last answer option is open ended because an individual with three cars would be in the same category as someone who owned 50 cars. As such, it is impossible to accurately calculate the mean number of

cars owned. However, it is possible to calculate the median response. For the above example, the median would be two cars owned.

A final condition in which one should use the median instead of the mean is when one has incomplete information. If one were collecting survey information, and some of the participants refused or forgot to answer a question, one would have responses from some participants but not others. It would not be possible to calculate the mean in this instance, as one is missing important information that could change the mean that would be calculated if the missing information were known.

Mode

The mode is well suited to be used to measure the central tendency of variables measured at the nominal level. Because variables measured at the nominal level are given labels, then any number assigned to these variables does not measure quantity. As such, it would be inappropriate to use the mean or the median with variables measured at this level, as both of those measures of central tendency require calculations involving quantity. The mode should also be used when finding the middle of distribution of a discrete variable. As these variables exist only in whole numbers, using other methods of central tendency may result in fractions of numbers, making it difficult to interpret the results. A common example of this is the saying, “The average family has a mom, a dad, and 2.5 kids.” People are discrete variables, and as such, they should never be measured in such a way as to obtain decimal results. The mode can also be used to provide additional information, along with other calculations of central tendency. Information about the location of the mode compared with the mean can help determine whether the distribution they are both calculated from is skewed.

CENTRALITY

Centrality metrics are metrics in (social) network analysis that are used to identify the significance of nodes in a network. In this entry, the centrality metrics are defined and contextualized in network research. Three variants of centrality metrics, which are especially prevalent in the literature, are discussed in detail: degree centrality, betweenness centrality, and closeness centrality. The existence of alternative calculations and metrics based on the presented centrality measures are also discussed.

Many studies in network analysis endeavor to describe the structure of networks or investigate how different positions of nodes within these structures lead to certain outcomes for these nodes. For example, one may describe and compare social structures within different classes of a school in a study about classroom climate, or one may analyze trade networks to establish whether certain core trade partners exist that successfully turn their position into a financial benefit.

Among others, these types of research questions ask for a structural parameter that we call centrality. Centrality defines—and operationalizes—who is more in the center of a network and who is more at the periphery. This seemingly simple question has evoked a discussion in the social network literature that spans many decades. Researchers have concluded that there is no single measure that captures this feature of a network, but it depends on the nature of the network and the research question at hand. Hence, multiple variants and subvariants of centrality measures exist. The ones that are most often used are degree centrality, betweenness centrality, and closeness centrality. All three are briefly discussed in the following sections. Information on variants of these measures used with different types of network data can be found in the readings listed at the end of the entry.

Degree Centrality

Degree centrality is arguably the simplest of the three centrality measures covered here. In an undirected

network, it is the (weighted) count of ties that one node is involved with. In an exemplary network, where B is connected to A and C without any other ties being present, B has an (unweighted) degree centrality of two, while A and C (each) have a degree centrality of one. If we had a directed network, degree centrality could be further broken down into out-degree centrality (the [weighted] number of outgoing ties) and in-degree centrality (the [weighted] number of incoming ties). When following this definition of degree centrality, no further structural information about a network is needed. For instance, the researcher does not need to know how the nodes and ties are distributed beyond a node's immediate neighbors. This makes degree centrality also more easily applicable to egocentric network data.

Betweenness Centrality

Betweenness centrality is a centrality metric that is based on the assumption that not only the raw count of ties matters, but ties are of quite different importance, depending on whether they create nonredundant connections between parts of the network. Put differently, a person that takes a broker position between two parties has an important role, even if he or she does not have a high absolute number of ties. This is also reflected in the computation of betweenness centrality, which is a count of the times one node is an element of the shortest path that connects other nodes.

Closeness Centrality

Closeness centrality is a centrality measure that, too, is based on the identification of shortest paths. Contrary to betweenness centrality, closeness centrality means the average of the shortest path length from the focal node to all other nodes in the network. Here, the most central node is an actor that has all other nodes as direct neighbors.

Variants and Normalization

While these three centrality measures have a long history and are used across the branches of network analysis, it is again imperative to highlight that multiple variants and alternative measures exist, because different types of networks follow different logics of when a node becomes important or central. Nonetheless, since these different conceptualizations of centrality are just variants of each other and are usually not entirely different, it is common to calculate and present multiple centrality measures next to each other.

The calculation of normalized metrics is prevalent in the literature too. Through this process of normalization, the size of the network is controlled and metrics from different networks can be compared with each other more easily. As presented here, all centrality measures describe attributes of individual nodes (often made explicit by labels such as “nodal degree”). It is worth mentioning that some of these metrics can be used to extract information from the network as a whole. For these network-level properties, the terms *centralization* or *graph centrality* are most commonly used.

CHANGING CRITERION DESIGN

The changing criterion design (CCD) is part of a compendium of research methods commonly referred to as *single-case* or *small-n designs*. Differing slightly from other single-case designs (SCDs), the goal of the CCD is to gradually increase or decrease the rate at which a single target behavior occurs. CCDs accomplish this goal by implementing a series of phases, each with a stepwise change in the rate of the target behavior required to meet the phase's criterion. Each phase can then be used as the subsequent phase's baseline. This entry details a brief history of the CCD, its experimental rigor, its defining features, and its common applications.

History

The first functional specification of the CCD appeared in a study by L. Weis and R. Vance Hall (1971)

described in the book, *Managing Behavior: Behavior Modification Applications in School and Home*. This application was health related and was implemented as a graduated procedure to reduce cigarette smoking behavior and nicotine addiction. Within 5 years of this original application, Donald P. Hartmann and Hall (1976) provided a more formal explanation of the CCD whereby general rules regarding design application were provided along with scientific explanations of experimental rigor. Once again, cigarette smoking was the targeted behavior. Although Hartmann and Hall conceptualized the CCD as a type of multiple baseline design (MBD), this notion would be challenged first by John O. Cooper and colleagues in 2007 and more recently by Liesa A. Klein and colleagues in 2017. The latter study provided data indicating the CCD shares a much stronger relationship with variations in A-B types of designs. This view is echoed and extended by the What Works Clearinghouse (WWC, 2020) which suggests that in conducting research utilizing a CCD, WWC standards regarding reversal or withdrawal (i.e., ABAB) should be adhered to. While it is very unusual for a withdrawal to be incorporated into a CCD design, reversals (more commonly mini-reversals) are common, as they add an element of experimental control to the CCD. The WWC states

Each . . . intervention change or criterion change should be considered a phase change. As such, there should be at least three different criterion changes to establish three attempts to demonstrate an intervention effect. (WWC, 2020, pp. 80–81)

This is important in that many textbook descriptions of CCDs suggest the outdated assumption that two criterion changes are sufficient.

Although the CCD was used infrequently in research applications in the 1970s through the 1990s, a series of articles by Dennis McDougall, in 2005 and 2006, presented a case for expanded use and utility of the design. This spurred renewed interest in the design and broadened its acceptance within health-related fields along with reaffirming its already established utility in education.

Experimental Control Using the CCD

Liesa Klein and colleagues conducted a 2017 review of the CCD, and found that nearly all applications of CCDs in the literature have shown acceptable clinical significance, which is the therapeutic goal. However, there are numerous studies—in fact a majority—that appear indifferent to a lack of experimental control within the CCD. Failure to implement measures to increase

experimental control detracts from the ability to demonstrate intervention utility or make valid appraisals. Fortunately, like other small-*n* SCDs, CCDs are able to neutralize threats to internal and external validity with well-controlled applications and robust results.

Although the majority of SCDs depend on a robust and observable change concurrent with the implementation of an intervention (e.g., A-B, A-B-A, A-B-A-B, MBD), the graduated implementation of the treatment and the expected adherence to a set criterion set the CCD apart from this norm. Whereas experimental control is determined by robust changes at or near the point of phase changes in most SCDs, adherence to each set criterion level is the crucial element for demonstrating experimental control in a CCD.

Klein and colleagues suggest enforcing criterion compliance and utilizing mini-reversals whenever practical to experimentally strengthen the CCD. Mini-reversals also add to experimental rigor of the CCD. A mini-reversal typically consists of backing off to a previous criterion level. Other features that bolster displays of experimental control include varying phase lengths and varying criterion change magnitudes; both show that the treatment and criterion are guiding performance, which boosts treatment confidence and experimental control.

A Walkthrough on How to Implement a CCD

A CCD is a suitable choice when the goal is to gradually decrease or increase the rate at which a targeted behavior or criterion is exhibited. Practitioners should therefore make certain that it is feasible and ethical to change the behavior in a graduated (i.e., stepwise) fashion. For example, a behavior that poses an immediate danger to a subject (e.g., self-injury) or might best be resolved rapidly (e.g., disruptive behavior) should be treated with a more robust approach such as MBD or A-B variation.

A hypothetical example of how a CCD can be implemented to decrease a target behavior is presented in Figure 1. The person in this hypothetical example wishes to decrease the frequency at which they check their social media accounts because of the associated time commitment. One of the critical determinations that a practitioner must make prior to implementation is where to set the first criterion level. Helpful suggestions to guide this decision are provided by Paul A. Alberto and Anne C. Troutman (2006). To carry out any of the following suggestions, one must first establish a baseline. Preferably this would be at least five to seven data points devoid of deterioration or unwanted trends, especially in the direction of the desired

Figure 1 A Hypothetical Example of a CCD Being Implemented Used to Gradually Decrease Social Media Checking Behavior in an Individual Who Desires to Decrease Excessive Checking of Social Media Applications

Note: The behavior was not removed completely (i.e., decreased to zero frequency) because checking at a lesser frequency is not necessarily maladaptive. Several features were included to maximize experimental control including a mini-reversal at the fourth criterion, varied phase lengths of the criteria, and variation in the magnitudes of criterion change.

outcome. Following the establishment of a baseline, recommended options for setting the first criterion level include calculating and using the mean of the baseline, halving the baseline mean and using that, using the high or low point of the baseline (depending on directionality), or seeking the opinion of a person with training and knowledge of the disorder to set the criterion. Although it is important for the person to have the capacity to change in their repertoire (as demonstrated in baseline responses), generally consulting a person with training for an estimate is the most feasible option.

As suggested by WWC, in order to meet expectations for demonstrating experimental control, three criterion shift phases are required and the number of data points in each phase should be at least five when possible. Success in meeting the criterion level, especially in the first phase, is essential. If the criterion is not achieved for one or several points, one can extend the phase until the criterion is met and is stable or one can retreat the target criterion toward the baseline for the next phase. The goal is to meet the criterion (not to beat it). If a subject significantly beats or surpasses the target criterion, the experimental objective of the CCD is defeated and one should consider another design such as A-B or MBD where a robust change is desired as an alternative.

Phase and criterion shifts should continue until the desired performance level is reached. As noted in the hypothetical example, it is not always the case that the goal would be to completely eliminate a behavior. Likewise, when increasing a behavior, perfect performance might not be feasible or desired. Also, Figure 1 notes the use of a mini-reversal, varying phase lengths, and varying criterion change magnitudes, all of which allow for stricter control.

The Range-Bound Changing Criterion Design

In 2005 and 2006, two variations on the CCD were introduced by McDougall. One in particular, the *range-bound changing criterion design* (RBCCD), shows promise as a useful tool for applied researchers. In a RBCCD, two criteria are used in each intervention phase to bracket preestablished acceptable performance levels. Adherence to the two criteria (i.e., staying consistently between them) demonstrates acceptable experimental control, and it is essential that these be preset.

It is often very difficult, if not impossible, for certain singular criterion to be adhered to exactly. For example, setting a specific caffeine intake criterion in milligrams might present a target that is hard to hit exactly throughout an intervention, whereas a range is much

more feasible. Likewise, with physical activity levels setting upper and lower criteria might effectively prevent overtraining or injury. There is much potential for using the RBCCD in both educational and health-related interventions.

Parametric Variation Versus CCD

CCDs should be distinguished from designs that use parametric variations of the AB design. Although the two designs share commonalities and changing the parameters of an intervention can at times be conceptualized to be a criterion shift, there are significant differences. Most commonly used in medical research, parametric variations of the AB design seek to answer the question: How much of the independent variable will cause how much change in the dependent variable? To this end, parametric variations systematically increase or decrease the amount of the intervention dispensed at one time while tracking subsequent changes in the dependent variable. In other words, the form of treatment itself does not change between phases, nor would the expected outcomes “predictably change.” Instead, the amount of treatment dispensed or implemented varies by phase and the outcome is not set, but rather is wait and see. Contrastingly, the CCD does not change the dispensation or implementation of the intervention. The intervention remains consistent at each phase while the criterion for receiving certain consequences changes in each new phase. Further, the behavior change outcome for each phase is predicted to match the set criterion for that phase.

Despite these important differences, the two designs share some similar features. Both promote incremental changes in the dimension of a behavior rather than the topography of a behavior. For instance, both designs might expect that the measured behavior will decrease in frequency at each phase, but neither would expect a new behavior to appear that did not previously exist in the individual’s repertoire. These designs also share an important advantage such that withdrawal of the intervention is not required to demonstrate experimental control. In these designs, each phase is used as the subsequent phase’s baseline so that experimental control can be demonstrated as the measured behavior covaries with changes to the intervention. This allows for continuous implementation of the intervention, an advantage absent in other SCDs that require withdrawal of treatment to demonstrate experimental control.

Shaping Behaviors and the CCD

Using CCDs to shape behavior has garnered differing levels of support over time. Given that the CCD is

characterized by reinforcement of stepwise changes in behavior, original descriptions of the CCD (Hall & Fox, 1977; Hartmann & Hall, 1976) assert that the design is ideal for demonstrating the effectiveness of shaping procedures. The design would then need to function as an MBD across behaviors because shaping requires the stepwise acquisition of topographically different behavior approximations. However, the CCD is intended to manipulate a dimension of a single target behavior that already exists in an individual's repertoire. Therefore, each phase in a CCD should contain manipulation of the same target behavior. This is not conducive to demonstrating the effectiveness of shaping procedures as they require topographically diverse behaviors across phases, negating the use of one phase as the previous phase's baseline. Further, in shaping procedures, new behavior approximations depend on previous behavior approximations. This interdependence limits implementation of certain CCD features, such as mini-reversals and phase length variations, that demonstrate experimental control. Contrary to original ideas about using the CCD to shape behaviors, current reviews (Klein et al., 2017) find that the CCD is most appropriate for the deceleration and acceleration of a dimension of a single target behavior.

Applications in Education

The CCD has been frequently utilized as a classroom intervention. The majority of the published interventions utilizing a CCD appear in behavioral and educational journals (see Klein et al., 2017). Several features of the CCD make it an ideal design for application in a classroom. Academic behaviors, such as time spent reading, are rarely considered dangerous or life-threatening and therefore can be altered gradually without ethical concerns. In addition, as mentioned earlier, withdrawal of the treatment is not required for demonstrating experimental control in a CCD. This is ideal for classroom environments in which removing treatment is undesirable or not feasible and where graduated improvements across academic terms are desired. Common applications in the classroom target academic behaviors such as on-task behavior, productivity or assignment completion, or assignment accuracy. Smaller, stepwise changes are ideal for altering these behaviors, making the CCD especially fitting.

Final Considerations

A criterion is a system or standard by which something can be assessed. The broad interpretations of the

term probably contribute to some confusion regarding the application and goals of the CCD. With broader application and acceptance, the roles played by the CCD in therapy and research will gain clarity. The CCD has several unique features that distinguish it from other SCDs. Primarily, it has the potential to be experimentally rigorous while demonstrating incremental changes in behavior without the removal of the treatment. This makes the CCD ideal for clinical and real-world applications that result in therapeutic changes to behavior.

CHI-SQUARE TEST

The chi-square test is a nonparametric test of the statistical significance of a relation between two nominal or ordinal variables. Because a chi-square analyzes grosser data than do parametric tests such as *t* tests and analyses of variance (ANOVAs), the chi-square test can report only whether groups *in a sample* are significantly different in some measured attribute or behavior; it does not allow one to generalize from the sample to the population from which it was drawn. Nonetheless, because chi-square is less “demanding” about the data it will accept, it can be used in a wide variety of research contexts. This entry focuses on the application, requirements, computation, and interpretation of the chi-square test, along with its role in determining associations among variables.

Bivariate Tabular Analysis

Though one can apply the chi-square test to a single variable and judge whether the frequencies for each category are equal (or as expected), a chi-square is applied most commonly to frequency results reported in bivariate tables, and interpreting bivariate tables is crucial to interpreting the results of a chi-square test. Bivariate tabular analysis (sometimes called *crossbreak analysis*) is used to understand the relationship (if any) between two variables. For example, if a researcher wanted to know whether there is a relationship between the gender of U.S. undergraduates at a particular university and their footwear preferences, he or she might ask male and female students (selected as randomly as possible), “On average, do you prefer to wear sandals, sneakers, leather shoes, boots, or something

else?” In this example, the independent variable is gender and the dependent variable is footwear preference. The independent variable is the quality or characteristic that the researcher hypothesizes helps to predict or explain some other characteristic or behavior (the dependent variable). Researchers control the independent variable (in this example, by sampling males and females) and elicit and measure the dependent variable to test their hypothesis that there is some relationship between the two variables.

To see whether there is a systematic relationship between gender of undergraduates at University X and reported footwear preferences, the results could be summarized in a table as shown in Table 1.

Each cell in a bivariate table represents the intersection of a value on the independent variable and a value on the dependent variable by showing how many times that combination of values was observed in the sample being analyzed. Typically, in constructing bivariate tables, values on the independent variable are arrayed on the vertical axis, while values on the dependent variable are arrayed on the horizontal axis. This allows one to read “across,” from values on the independent variable to values on the dependent variable. (Remember, an observed relationship between two variables is not necessarily causal.)

Reporting and interpreting bivariate tables is most easily done by converting raw frequencies (in each cell) into percentages of each cell within the categories of the independent variable. Percentages basically standardize cell frequencies as if there were 100 subjects or observations in each category of the independent variable. This is useful for comparing across values on the independent variable if the raw row totals are close to or more than 100, but increasingly dangerous as raw row totals become smaller. (When reporting

Table 1 Male and Female Undergraduate Footwear Preferences at University X (Raw Frequencies)

<i>Group</i>	<i>Sandals</i>	<i>Sneakers</i>	<i>Leather Shoes</i>	<i>Boots</i>	<i>Other</i>
Male	6	17	13	9	5
Female	13	5	7	16	9

Table 2 Male and Female Undergraduate Footwear Preferences at University X (Percentages)

<i>Group</i>	<i>Sandals</i>	<i>Sneakers</i>	<i>Leather Shoes</i>	<i>Boots</i>	<i>Other</i>	<i>N</i>
Male	12	34	26	18	10	50
Female	26	10	14	32	18	50

percentages, one should indicate total N at the end of each row or independent variable category.)

Table 2 shows that in this sample roughly twice as many women as men preferred sandals and boots, about 3 times more men than women preferred sneakers, and twice as many men as women preferred leather shoes. One might also infer from the “Other” category that female students in this sample had a broader range of footwear preferences than did male students.

Converting raw observed values or frequencies into percentages allows one to see patterns in the data more easily, but how confident can one be that those apparent patterns actually reflect a systematic relationship in the sample between the variables (between gender and footwear preference, in this example) and not just a random distribution?

Chi-Square Requirements

The chi-square test of statistical significance is a series of mathematical formulas that compare the actual observed frequencies of the two variables measured in a sample with the frequencies one would expect if there were no relationship at all between those variables. That is, chi-square assesses whether the actual results are different enough from the null hypothesis to overcome a certain probability that they are due to sampling error, randomness, or a combination.

Because chi-square is a nonparametric test, it does not require the sample data to be at an interval level of measurement and more or less normally distributed (as parametric tests such as t tests do), although it does rely on a weak *assumption* that each variable’s values are normally distributed in the population from which the sample is drawn. But chi-square, while forgiving, does have some requirements:

1. *Chi-square is most appropriate for analyzing relationships among nominal and ordinal variables.* A nominal variable (sometimes called a categorical variable) describes an attribute in terms of mutually exclusive, nonhierarchically related categories, such as gender and footwear preference. Ordinal variables measure an attribute (such as military rank) that subjects may have more or less of but that cannot be measured in equal increments on a scale. (Results from interval variables, such as scores on a test, would have to first be grouped before they could “fit” into a bivariate table and be analyzed with chi-square; this grouping loses much of the incremental information of the original scores, so interval data are usually analyzed using parametric tests such as ANOVAs and t tests. The relationship between two ordinal variables is usually best analyzed with a Spearman rank order correlation.)
2. *The sample must be randomly drawn from the population.*
3. *Data must be reported in raw frequencies—not, for example, in percentages.*
4. *Measured variables must be independent of each other.* Any observation must fall into *only one* category or value on each variable, and no category can be inherently dependent on or influenced by another.
5. *Values and categories on independent and dependent variables must be mutually exclusive and exhaustive.* In the footwear data, each subject is counted only once, as either male or female and as preferring sandals, sneakers, leather shoes, boots, or other kinds of footwear. For some variables, no “other” category may be needed, but often “other” ensures that the variable has been exhaustively categorized. (Some kinds of analysis may require an “uncodable” category.) In any case, the results for the whole sample must be included.
6. *Expected (and observed) frequencies cannot be too small.* Chi-square is based on the expectation that *within any category*, sample frequencies are normally distributed about the expected population value. Since frequencies of occurrence cannot be negative, the distribution cannot be normal when expected population values are close to zero (because the sample frequencies cannot be much *below* the expected frequency while they *can* be much above it). When expected frequencies are large, there is no problem with the assumption of normal distribution, but the smaller the expected frequencies, the less valid the results of the chi-square test. In addition, because some of the mathematical formulas in chi-square use division, no cell in a table can have an observed raw frequency of zero.

The following minimums should be obeyed:

For a 1×2 or 2×2 table, expected frequencies in each cell should be at least 5.

For larger tables (2×4 or 3×3 or larger), if all expected frequencies but one are at least 5 and if the one small cell is at least 1, chi-square is appropriate. In general, the greater the degrees of freedom (i.e., the more values or categories on the independent and dependent variables), the more lenient the minimum expected frequencies threshold.

1. *Chi-square is most appropriate for analyzing relationships among nominal and ordinal variables.* A nominal variable (sometimes called a categorical variable) describes an attribute in terms of mutually exclusive, nonhierarchically related categories, such as gender and footwear preference. Ordinal variables measure an attribute (such as military rank) that subjects may have more or less of but that cannot be measured in equal increments on a scale. (Results from interval variables, such as scores on a test, would have to first be grouped before they could “fit” into a bivariate table and be analyzed with chi-square; this grouping loses much of the incremental information of the original scores, so interval data are usually analyzed using parametric tests such as

Sometimes, when a researcher finds low expected frequencies in one or more cells, a possible solution is to combine, or collapse, two cells together. (Categories on a variable cannot be excluded from a chi-square analysis; a researcher cannot arbitrarily exclude some subset of the data from analysis.) But a decision to collapse categories should be carefully motivated, preserving the integrity of the data as it was originally collected.

Computing the Chi-Square Value

The process by which a chi-square value is computed has four steps:

1. *Setting the p value.* This sets the threshold of tolerance for error. That is, what odds is the researcher willing to accept that apparent patterns in the data may be due to randomness or sampling error rather than some systematic relationship between the measured variables? The answer depends largely on the research question and the consequences of being wrong. If people's lives depend on the interpretation of the results, the researcher might want to take only one chance in 100,000 (or 1,000,000) of making an erroneous claim. But if the stakes are smaller, he or she might accept a greater risk—1 in 100 or 1 in 20. To minimize any temptation for post hoc compromise of scientific standards, researchers should explicitly motivate their threshold *before* they perform any test of statistical significance. For the footwear study, we

will set a probability of error threshold of 1 in 20, or $p < .05$.

2. *Totaling all rows and columns.* See Table 3.
3. *Deriving the expected frequency of each cell.* Chi-square operates by comparing the observed frequencies in each cell in the table to the frequencies one would expect if there were no relationship at all between the two variables in the populations from which the sample is drawn (the null hypothesis). The null hypothesis—the “all other things being equal” scenario—is derived from the observed frequencies as follows: The expected frequency in each cell is the product of that cell's row total multiplied by that cell's column total, divided by the sum total of all observations. So, to derive the expected frequency of the Males who prefer Sandals cell, multiply the top row total (50) by the first column total (19) and divide that product by the sum total (100): $((50 \times 19) / 100) = 9.5$. The logic of this is that we are deriving the expected frequency of each cell from the union of the total frequencies of the relevant values on each variable (in this case, Male and Sandals), as a proportion of all observed frequencies in the sample. This calculation produces the expected frequency of each cell, as shown in Table 4.

Now a comparison of the observed results with the results one would expect if the null hypothesis were true is possible. (Because the sample includes the same number of male and female subjects, the male and female expected scores are the same. This will not be

Table 3 Male and Female Undergraduate Footwear Preferences at University X: Observed Frequencies With Row and Column Totals

Group	Sandals	Sneakers	Leather Shoes	Boots	Other	Total
Male	6	17	13	9	5	50
Female	13	5	7	16	9	50
Total	19	22	20	25	14	100

Table 4 Male and Female Undergraduate Footwear Preferences at University X: Observed and Expected Frequencies

Group	Sandals	Sneakers	Leather Shoes	Boots	Other	Total
Male:observedexpected	69.5	1711	1310	912.5	57	50
Female:observedexpected	139.5	511	710	1612.5	97	50
Total	19	22	20	25	14	100

the case with unbalanced samples.) This table can be informally analyzed, comparing observed and expected frequencies in each cell (e.g., males prefer sandals less than expected), across values on the independent variable (e.g., males prefer sneakers more than expected, females less than expected), or across values on the dependent variable (e.g., females prefer sandals and boots more than expected, but sneakers and shoes less than expected). But some way to measure how different the observed results are from the null hypothesis is needed.

4. *Measuring the size of the difference between the observed and expected frequencies in each cell.* To do this, calculate the difference between the observed and expected frequency in each cell, square that difference, and then divide that product by the difference itself. The formula can be expressed as $(O - E)^2 / E$.

Squaring the difference ensures a positive number, so that one ends up with an absolute value of differences. (If one did not work with absolute values, the positive and negative differences across the entire table would always add up to 0.) Dividing the squared difference by the expected frequency essentially removes the expected frequency from the equation, so that the remaining measures of observed versus expected difference are comparable across all cells.

So, for example, the difference between observed and expected frequencies for the Male–Sandals preference is calculated as follows:

1. Observed (6) – Expected (9.5) = Difference (–3.5)
2. Difference (–3.5) squared = 12.25
3. Difference squared (12.25) / Expected (9.5) = 1.289

The sum of all products of this calculation on each cell is the total chi-square value for the table: 14.026.

Interpreting the Chi-Square Value

Now the researcher needs some criterion against which to measure the table's chi-square value in order to tell whether it is significant (relative to the p value that has been motivated). The researcher needs to know the probability of getting a chi-square value of a given minimum size even if the variables are not related at all in the sample. That is, the researcher needs to know how much larger than zero (the chi-square value of the null hypothesis) the table's chi-square value must be before the null hypothesis can be

rejected with confidence. The probability depends in part on the complexity and sensitivity of the variables, which are reflected in the degrees of freedom of the table from which the chi-square value is derived.

A table's degrees of freedom (df) can be expressed by this formula: $df = (r - 1)(c - 1)$. That is, a table's degrees of freedom equals the number of rows in the table minus 1, multiplied by the number of columns in the table minus 1. (For 1×2 tables, $df = k - 1$, where k = number of values or categories on the variable.) Different chi-square thresholds are set for relatively gross comparisons (1×2 or 2×2) versus finer comparisons. (For Table 1, $df = (2 - 1)(5 - 1) = 4$.)

In a statistics book, the sampling distribution of chi-square (also known as *critical values of chi-square*) is typically listed in an appendix. The researcher can read down the column representing his or her previously chosen probability of error threshold (e.g., $p < .05$) and across the row representing the degrees of freedom in his or her table. If the researcher's chi-square value is larger than the critical value in that cell, his or her data represent a statistically significant relationship between the variables in the table. (In statistics software programs, all the computations are done for the researcher, and he or she is given the exact p value of the results.)

Table 1's chi-square value of 14.026, with $df = 4$, is greater than the related critical value of 9.49 (at $p = .05$), so the null hypothesis can be rejected, and the claim that the male and female undergraduates at University X in this sample differ in their (self-reported) footwear preferences and that there is some relationship between gender and footwear preferences (in this sample) can be affirmed.

A statistically significant chi-square value indicates the degree of confidence a researcher may hold that the relationship between variables in the sample is systematic and not attributable to random error. It does not help the researcher to interpret the nature or explanation of that relationship; that must be done by other means (including bivariate tabular analysis and qualitative analysis of the data).

Measures of Association

By itself, statistical significance does not ensure that the relationship is theoretically or practically important or even very large. A large enough sample may demonstrate a statistically significant relationship between two variables, but that relationship may be a trivially weak one. The relative strength of association of a statistically significant relationship between the variables in the data can be derived from a table's chi-square value.

For tables larger than 2×2 (such as Table 1), a measure called Cramer's V is derived by the following formula (where N = the total number of observations, and k = the smaller of the number of rows or columns):

$$\text{Cramer's } V = \text{the square root of} \\ (\text{chi-square divided by } (N \text{ times } (k \text{ minus } 1)))$$

So, for Table 1, Cramer's V can be computed as follows:

1. $N(k-1) = 100(2-1) = 100$
2. $\text{Chi-square}/100 = 14.026/100 = 0.14$
3. $\text{Square root of } 0.14 = 0.37$

The product is interpreted as a Pearson correlation coefficient (r). (For 2×2 tables, a measure called *phi* is derived by dividing the table's chi-square value by N (the total number of observations) and then taking the square root of the product. *Phi* is also interpreted as a Pearson r .) Also, r^2 is a measure called *shared variance*. Shared variance is the portion of the total representation of the variables measured in the sample data that is accounted for by the relationship measured by the chi-square. For Table 1, $r^2 = .137$, so approximately 14% of the total footwear preference story is accounted for by gender.

A measure of association like Cramer's V is an important benchmark of just "how much" of the phenomenon under investigation has been accounted for. For example, Table 1's Cramer's V of 0.37 ($r^2 = .137$) means that there are one or more variables remaining that, cumulatively, account for at least 86% of footwear preferences. This measure, of course, does not begin to address the nature of the relation(s) among these variables, which is a crucial part of any adequate explanation or theory.

CLASSICAL TEST THEORY

Measurement is the area of quantitative social science that is concerned with ascribing numbers to individuals in a meaningful way. Measurement is distinct from statistics, though measurement theories are grounded in applications of statistics. Within measurement there are several theories that allow us to talk about the quality of measurements taken. Classical test theory (CTT) can arguably be described as the first formalized theory of measurement and is still the most commonly used method of describing the characteristics of assessments. With test theories, the term *test* or *assessment* is applied widely. Surveys, achievement tests, intelligence tests, psychological assessments, writing samples graded with rubrics, and innumerable other situations in which numbers are assigned to individuals can all be considered tests. The terms *test*, *assessment*, *instrument*, and *measure* are used interchangeably in this discussion of CTT. After a brief discussion of the early history of CTT, this entry provides a formal definition and discusses CTT's role in reliability and validity.

Early History

Most of the central concepts and techniques associated with CTT (though it was not called that at the time) were presented in papers by Charles Spearman in the early 1900s. One of the first texts to codify the emerging discipline of measurement and CTT was Harold Gulliksen's *Theory of Mental Tests*. Much of what Gulliksen presented in that text is used unchanged today. Other theories of measurement (generalizability theory, item response theory) have emerged that address some known weaknesses of CTT (e.g., homoscedasticity of error along the test score distribution). However, the comparative simplicity of CTT and its continued utility

in the development and description of assessments have resulted in CTT's continued use. Even when other test theories are used, CTT often remains an essential part of the development process.

Formal Definition

CTT relies on a small set of assumptions. The implications of these assumptions build into the useful CTT paradigm. The fundamental assumption of CTT is found in the equation

$$X = T + E, \quad (1)$$

where X represents an observed score, T represents true score, and E represents error of measurement.

The concept of the true score, T , is often misunderstood. A true score, as defined in CTT, does not have any direct connection to the construct that the test is intended to measure. Instead, the true score represents the number that is the *expected* value for an individual based on this specific test. Imagine that a test taker took a 100-item test on world history. This test taker would get a score, perhaps an 85. If the test was a multiple-choice test, probably some of those 85 points were obtained through guessing. If given the test again, the test taker might guess better (perhaps obtaining an 87) or worse (perhaps obtaining an 83). The causes of differences in observed scores are not limited to guessing. They can include anything that might affect performance: a test taker's state of being (e.g., being sick), a distraction in the testing environment (e.g., a humming air conditioner), or careless mistakes (e.g., misreading an essay prompt).

Note that the true score is theoretical. It can never be observed directly. Formally, the true score is assumed to be the expected value (i.e., average) of X , the observed score, over an infinite number of independent administrations. Even if an examinee could be given the same test numerous times, the administrations would not be independent. There would be practice effects, or the test taker might learn more between administrations.

Once the true score is understood to be an average of observed scores, the rest of Equation 1 is straightforward. A scored performance, X , can be thought of as deviating from the true score, T , by some amount of error, E . There are additional assumptions related to CTT: T and E are uncorrelated ($\rho_{TE} = 0$), error on one test is uncorrelated with the error on another test ($\rho_{E_1E_2} = 0$), and error on one test is uncorrelated with the true score on another test ($\rho_{E_1E_2} = 0$). These assumptions will not be elaborated on here, but they are used in the derivation of concepts to be discussed.

Reliability

If E tends to be large in relation to T , then a test result is inconsistent. If E tends to be small in relation to T , then a test result is consistent. The major contribution of CTT is the formalization of this concept of consistency of test scores. In CTT, test score consistency is called *reliability*. Reliability provides a framework for thinking about and quantifying the consistency of a test. Even though reliability does not directly address constructs, it is still fundamental to measurement. The often used bathroom scale example makes the point. Does a bathroom scale accurately reflect weight? Before establishing the scale's accuracy, its consistency can be checked. If one were to step on the scale and it said 190 pounds, then step on it again and it said 160 pounds, the scale's lack of utility could be determined based strictly on its inconsistency.

Now think about a formal assessment. Imagine an adolescent was given a graduation exit exam and she failed, but she was given the same exam again a day later and she passed. She did not learn in one night everything she needed in order to graduate. The consequences would have been severe if she had been given only the first opportunity (when she failed). If this inconsistency occurred for most test takers, the assessment results would have been shown to have insufficient consistency (i.e., reliability) to be useful. Reliability coefficients allow for the quantification of consistency so that decisions about utility can be made.

T and E cannot be observed directly for individuals, but the relative contribution of these components to X is what defines reliability. Instead of direct observations of these quantities, group-level estimates of their variability are used to arrive at an estimate of reliability. Reliability is usually defined as

$$\rho_{XX'} = \frac{\sigma_T^2}{\sigma_X^2} = \frac{\sigma_T^2}{\sigma_T^2 + \sigma_E^2}, \quad (2)$$

where X , T , and E are defined as before. From this equation one can see that reliability is the ratio of true score variance to observed score variance within a sample. Observed score variance is the only part of this equation that is observable. There are essentially three ways to estimate the unobserved portion of this equation. These three approaches correspond to three distinct types of reliability: *stability reliability*, *alternate-form reliability*, and *internal consistency*.

All three types of reliability are based on correlations that exploit the notion of parallel tests. Parallel tests are defined as tests having equal true scores ($T = T'$) and equal error variance ($\sigma_E^2 = \sigma_{E'}^2$) and meeting all other assumptions of CTT. Based on these assumptions, it can be derived (though it will not be

shown here) that the correlation between parallel tests provides an estimate of reliability (i.e., the ratio of true score variance to observed score variance). The correlation among these two scores is the observed reliability coefficient ($r_{XX'}$). The correlation can be interpreted as the proportion of variance in observed scores that is attributable to true scores; thus $r_{XX'} = r_{XT}^2$. The type of reliability (stability reliability, alternate-form reliability, internal consistency) being estimated is determined by how the notion of a parallel test is established.

The most straightforward type of reliability is stability reliability. Stability reliability (often called test-retest reliability) is estimated by having a representative sample of the intended testing population take the same instrument twice. Because the same test is being used at both measurement opportunities, the notion of parallel tests is easy to support. The same test is used on both occasions, so true scores and error variance should be the same. Ideally, the two measurement opportunities will be close enough that examinees have not changed (learned or developed on the relevant construct). You would not, for instance, want to base your estimates of stability reliability on pretest-intervention-posttest data. The tests should also not be given too close together in time; otherwise, practice or fatigue effects might influence results. The appropriate period to wait between testing will depend on the construct and purpose of the test and may be anywhere from minutes to weeks.

Alternate-form reliability requires that each member of a representative sample respond on two alternate assessments. These alternate forms should have been built to be purposefully parallel in content and scores produced. The tests should be administered as close together as is practical, while avoiding fatigue effects. The correlation among these forms represents the alternate-form reliability. Higher correlations provide more confidence that the tests can be used interchangeably (comparisons of means and standard deviations will also influence this decision).

Having two administrations of assessments is often impractical. Internal consistency reliability methods require only a single administration. There are two major approaches to estimating internal consistency: split half and coefficient alpha. Split-half estimates are easily understood but have mostly been supplanted by the use of coefficient alpha. For a split-half approach, a test is split into two halves. This split is often created by convenience (e.g., all odd items in one half, all even items in the other half). The split can also be made more methodically (e.g., balancing test content and item types). Once the splits are obtained, the scores from the two halves are correlated. Conceptually, a single test is being used to create an estimate of

alternate-form reliability. For reasons not discussed in this entry, the correlation from a split-half method will underestimate reliability unless it is corrected.

The *Spearman-Brown prophecy formula* for predicting the correlation that would have been obtained if each half had been as long as the full-length test is given by

$$\rho_{XX'} = \frac{2\rho_{AB}}{1 + \rho_{AB}}, \quad (3)$$

where ρ_{AB} is the original correlation between the test halves and $\rho_{XX'}$ is the corrected reliability. If, for example, two test halves were found to have a correlation of .60, the actual reliability would be

$$\rho_{XX'} = \frac{2(.60)}{1 + .60} = \frac{1.20}{1.60} = .75.$$

As with all the estimates of reliability, the extent to which the two measures violate the assumption of parallel tests determines the accuracy of the result.

One of the drawbacks of using the split-half approach is that it does not produce a unique result. Other splits of the test will produce (often strikingly) different estimates of the internal consistency of the test. This problem is ameliorated by the use of single internal consistency coefficients that provide information similar to split-half reliability estimates. Coefficient alpha (often called Cronbach's alpha) is the most general (and most commonly used) estimate of internal consistency. The Kuder-Richardson 20 (KR-20) and 21 (KR-21) are reported sometimes, but these coefficients are special cases of coefficient alpha and do not require separate discussion. The formula for coefficient alpha is

$$\rho_{XX'} \geq \alpha = \frac{k}{k-1} \left(1 - \frac{\sum \sigma_i^2}{\sigma_X^2} \right), \quad (4)$$

where k is the number of items, σ_i^2 is the variance of item i , and σ_X^2 is the variance of test X . Coefficient alpha is equal to the average of all possible split-half methods computed using Phillip Rulon's method (which uses information on the variances of total scores and the differences between the split-half scores). Coefficient alpha is considered a conservative estimate of reliability that can be interpreted as a lower bound to reliability. Alpha is one of the most commonly reported measures of reliability because it requires only a single test administration.

Although all three types of reliability are based on the notions of parallel tests, they are influenced by distinct types of error and, therefore, are not interchangeable. Stability reliability measures the extent to which

occasions influence results. Errors associated with this type of reliability address how small changes in examinees or the testing environment impact results. Alternate-form reliability addresses how small differences in different versions of tests may impact results. Internal consistency addresses the way in which heterogeneity of items limits the information provided by an assessment. In some sense, any one coefficient may be an overestimate of reliability (even alpha, which is considered to be conservative). Data collected on each type of reliability would yield three different coefficients that may be quite different from one another. Researchers should be aware that a reliability coefficient that included all three sources of error at once would likely be lower than a coefficient based on any one source of error. *Generalizability theory* is an extension of CTT that provides a framework for considering multiple sources of error at once. Generalizability coefficients will tend to be lower than CTT-based reliability coefficients but may more accurately reflect the amount of error in measurements. Barring the use of generalizability theory, a practitioner must decide what types of reliability are relevant to his or her research and make sure that there is evidence of that type of consistency (i.e., through consultation of appropriate reliability coefficients) in the test results.

Validity Investigations and Research With Classical Test Theory

CTT is mostly a framework for investigating reliability. Most treatments of CTT also include extensive descriptions of validity; however, similar techniques are used in the investigation of validity whether or not CTT is the test theory being employed. In short hand, validity addresses the question of whether test results provide the intended information. As such, validity evidence is primary to any claim of utility. A measure can be perfectly reliable, but it is useless if the intended construct is not being measured. Returning to the bathroom scale example, if a scale always describes one adult of average build as 25 pounds and second adult of average build as 32 pounds, the scale is reliable. However, the scale is not accurately reflecting the construct *weight*.

Many sources provide guidance about the importance of validity and frameworks for the types of data that constitute validity evidence. More complete treatments can be found in Samuel Messick's many writings on the topic. A full treatment is beyond the scope of this discussion. Readers unfamiliar with the current unified understanding of validity should consult a more complete reference; the topics to be addressed here might convey an overly simplified (and positivist) notion of validity.

Construct validity is the overarching principle in validity. It asks, Is the correct construct being measured? One of the principal ways that construct validity is established is by a demonstration that tests are associated with criteria or other tests that purport to measure the same (or related) constructs. The presence of strong associations (e.g., correlations) provides evidence of construct validity. Additionally, research agendas may be established that investigate whether test performance is affected by things (e.g., interventions) that should influence the underlying construct. Clearly, the collection of construct validity evidence is related to general research agendas. When one conducts basic or applied research using a quantitative instrument, two things are generally confounded in the results: (1) the validity of the instrument for the purpose being employed in the research and (2) the correctness of the research hypothesis. If a researcher fails to support his or her research hypothesis, there is often difficulty determining whether the result is due to insufficient validity of the assessment results or flaws in the research hypothesis.

One of CTT's largest contributions to our understanding of both validity investigations and research in general is the notion of reliability as an upper bound to a test's association with another measure. From Equation 1, observed score variance is understood to comprise a true score, T , and an error term, E . The error term is understood to be random error. Being that it is random, it cannot correlate with anything else. Therefore, the true score component is the only component that may have a nonzero correlation with another variable. The notion of reliability as the ratio of true score variance to observed score variance (Equation 2) makes the idea of reliability as an upper bound explicit. Reliability is the proportion of systematic variance in observed scores. So even if there were a perfect correlation between a test's true score and a perfectly measured criterion, the observed correlation could be no larger than the square root of the reliability of the test. If both quantities involved in the correlation have less than perfect reliability, the observed correlation would be even smaller. This logic is often exploited in the reverse direction to provide a correction for attenuation when there is a lack of reliability for measures used. The correction for attenuation provides an upper bound estimate for the correlation among true scores. The equation is usually presented as

$$\rho_{T_X T_Y} = \frac{\rho_{XY}}{\sqrt{\rho_{XX'}} \sqrt{\rho_{YY'}}} \quad (5)$$

where ρ_{XY} is the observed correlation between two measures and $\rho_{XX'}$ and $\rho_{YY'}$ are the respective

reliabilities of the two measures. This correction for attenuation provides an estimate for the correlation among the underlying constructs and is therefore useful whenever establishing the magnitude of relationships among constructs is important. As such, it applies equally well to many research scenarios as it does to attempts to establish construct validity. For instance, it might impact interpretation if a researcher realized that an observed correlation of .25 between two instruments which have internal consistencies of .60 and .65 represented a potential true score correlation of

$$\rho_{T_X T_Y} = \frac{.25}{\sqrt{.60} \sqrt{.65}} = .40$$

The corrected value should be considered an upper bound estimate for the correlation if all measurement error were purged from the instruments. Of course, such perfectly reliable measurement is usually impossible in the social sciences, so the corrected value will generally be considered theoretical.

Group-Dependent Estimates

Estimates in CTT are highly group dependent. Any evidence of reliability and validity is useful only if that evidence was collected on a group similar to the current target group. A test that is quite reliable and valid with one population may not be with another. To make claims about the utility of instruments, testing materials (e.g., test manuals or technical reports) must demonstrate the appropriateness and representativeness of the samples used.

Final Thoughts

CTT provides a useful framework for evaluating the utility of instruments. Researchers using quantitative instruments need to be able to apply fundamental concepts of CTT to evaluate the tools they use in their research. Basic reliability analyses can be conducted with the use of most commercial statistical software (e.g., SPSS—an IBM company, formerly called PASW® Statistics—and SAS).

CLINICAL SIGNIFICANCE

In treatment outcome research, statistically significant changes in symptom severity or end-state functioning have traditionally been used to demonstrate treatment efficacy. In more recent studies, the *effect size*, or magnitude of change associated with the experimental intervention, has also been an important consideration in data analysis and interpretation. To truly understand the impact of a research intervention, it is essential for the investigator to adjust the lens, or “zoom out,” to also examine other signifiers of change. Clinical significance is one such marker and refers to the meaningfulness, or impact of an intervention, on clients and others in their social environment. An intervention that is clinically significant must demonstrate substantial or, at least, reasonable benefit to the client or others, such as family members, friends, or coworkers. Benefits gained, actual or perceived, must be weighed against the costs of the intervention. These costs may include financial, time, or family burden. Some researchers use the term *practical significance* as a synonym for clinical significance because both terms consider the import of a research finding in everyday life. However, there are differences in the usage of the two terms. *Clinical significance* is typically constrained to treatment outcome or prevention studies whereas *practical significance* is used broadly across many types of psychological research, including cognitive neuroscience, developmental psychology, environmental psychology, and social psychology. This entry discusses the difference between statistical and clinical significance and describes methods for measuring clinical significance.

Statistical Significance Versus Clinical Significance

Statistically significant findings do not always correspond to the client's phenomenological experience or overall evaluation of beneficial impact. First, a research study may have a small effect size yet reveal statistically significant findings due to high power. This typically occurs when a large sample size has been used. Nevertheless, the clinical significance of the research findings may be trivial from the research participants' perspective. Second, in other situations, a moderate effect size may yield statistically significant results, yet the pragmatic benefit to the client in his or her everyday life is questionable. For example, children diagnosed with attention-deficit/hyperactivity disorder may participate in an intervention study designed to increase concentration and reduce disruptive behavior. The investigators conclude that the active intervention was beneficial on the basis of significant improvement on Connors Ratings Scale scores as well as significantly improved performance on a computerized test measuring sustained attention. The data interpretation is correct from a statistical point of view. However, the majority of parents view the intervention as inconsequential because their children continue to evidence a behavioral problem that disrupts home life. Moreover, most of the treated children see the treatment as "a waste of time" because they are still being teased or ostracized by peers. Despite significant sustained attention performance improvements, classroom teachers also rate the experimental intervention as ineffective because they did not observe meaningful changes in academic performance.

A third scenario is the case of null research findings in which there is also an inconsistency between statistical interpretation and the client or family perspective. For instance, an experimental treatment outcome study is conducted with adult trauma survivors compared with treatment as usual. Overall, the treatment-as-usual group performed superiorly to the new intervention. In fact, on the majority of post-traumatic stress disorder (PTSD) measures, the experimental group evidenced no statistical change from pre- to posttest. Given the additional costs of the experimental intervention, the investigators may decide that it is not worth further investigation. However, qualitative interviews are conducted with the participants. The investigators are surprised to learn that most participants receiving the intervention are highly satisfied although they continue to meet PTSD diagnostic criteria. The interviews demonstrate clinical significance among the participants, who perceive a noticeable reduction in the intensity of daily dissociative symptoms. These participants see the experimental intervention as quite

beneficial in terms of facilitating tasks of daily living and improving their quality of life.

When planning a research study, the investigator should consider *who* will evaluate clinical significance (client, family member, investigator, original treating therapist) and *what* factor(s) are important to the evaluator (changes in symptom severity, functioning, personal distress, emotional regulation, coping strategies, social support resources, quality of life, etc.). An investigator should also consider the cultural context and the rater's cultural expertise in the area under examination. Otherwise, it may be challenging to account for unexpected results. For instance, a 12-week mindfulness-based cognitive intervention for depressed adults is initially interpreted as successful in improving mindfulness skills, on the basis of statistically significant improvements on two dependent measures: scores on a well-validated self-report mindfulness measure and attention focus ratings by the Western-trained research therapists. The investigators are puzzled that most participants do not perceive mindfulness skill training as beneficial; that is, the training has not translated into noticeable improvements in depression or daily life functioning. The investigators request a second evaluation by two mindfulness experts—a non-Western meditation practitioner versed in traditional mindfulness practices and a highly experienced yoga practitioner. The mindfulness experts independently evaluate the research participants and conclude that culturally relevant mindfulness performance markers (postural alignment, breath control, and attentional focus) are very weak among participants who received the mindfulness intervention.

Measures

Clinical significance may be measured several ways, including subjective evaluation, absolute change (did the client evidence a complete return to premorbid functioning or how much has an individual client changed across the course of treatment without comparison with a reference group), comparison method, or societal impact indices. In most studies, the comparison method is the most typically employed strategy for measuring clinical significance. It may be used for examining whether the client group returns to a normative level of symptoms or functioning at the conclusion of treatment. Alternatively, the comparison method may be used to determine whether the experimental group statistically differs from an impaired group at the conclusion of treatment even if the experimental group has not returned to premorbid functioning. For instance, a treatment outcome study is conducted with adolescents diagnosed with bulimia nervosa. After completing the intervention, the investigators may

consider whether the level of body image dissatisfaction is comparable to that of a normal comparison group with no history of eating disorders, or the study may examine whether binge-purge end-state functioning statistically differs from a group of individuals currently meeting diagnostic criteria for bulimia nervosa.

The *Reliable Change Index*, developed by Neil Jacobson and colleagues, and *equivalence testing* are the most commonly used comparison method strategies. These comparative approaches have several limitations, however, and the reader is directed to the Further Readings for more information on the conceptual and methodological issues.

The tension between researchers and clinical practitioners will undoubtedly lessen as clinical significance is foregrounded in future treatment outcome studies. Quantitative and qualitative measurement of clinical significance will be invaluable in deepening our understanding of factors and processes that contribute to client transformation.

response. Examples of interventions used in clinical trials include drugs, surgery, medical devices, and education and subject management strategies. In each of these cases, clinical trials are conducted to evaluate both the beneficial and harmful effects of the new intervention on human subjects before it is made available to the population of interest. Special considerations for conducting clinical trials include subject safety and informed consent, subject compliance, and intervention strategies to avoid bias. This entry describes the different types of clinical trials and discusses ethics in relation to clinical trials.

Drug Development Trials

Clinical trials in drug development follow from laboratory experiments, usually involving in vitro experiments or animal studies. The traditional goal of a preclinical study is to obtain preliminary information on pharmacology and toxicology. Before a new drug may be used in human subjects, several regulatory bodies, such as the internal review board (IRB), Food and Drug Administration (FDA), and data safety monitoring board, must formally approve the study. Clinical trials in drug development are conducted in a sequential fashion and categorized as Phase I, Phase II, Phase III, and Phase IV trial designs. The details of each phase of a clinical trial investigation are well defined within a document termed a *clinical trial protocol*. The FDA provides recommendations for the structure of Phase I through III trials in several disease areas.

Phase I trials consist primarily of healthy volunteer and participant studies. The primary objective of a Phase I trial is to determine the maximum tolerated dose. Other objectives include determining drug metabolism and bioavailability (how much drug reaches the circulation system). Phase I studies generally are short-term studies that involve monitoring toxicities in small cohorts of participants treated at consistently higher dose levels of the new drug in order to estimate the maximum tolerated dose.

Phase II trials build on the Phase I results in terms of which dose level or levels warrant further investigation. Phase II trials are usually fairly small-scale trials. In cancer studies, Phase II trials traditionally involve a single dose with a surrogate end point for mortality, such as change in tumor volume. The primary comparison of interest is the effect of the new regimen versus established response rates. In other diseases, such as cardiology, Phase II trials may involve multiple dose levels and randomization. The primary goals of a Phase II trial are to determine the optimal method of administration and examine the potential efficacy of a new regimen. Phase II trials generally have longer

CLINICAL TRIAL

A clinical trial is a prospective study that involves human subjects in which an intervention is to be evaluated. In a clinical trial, subjects are followed from a well-defined starting point or baseline. The goal of a clinical trial is to determine whether a cause-and-effect relationship exists between the intervention and

follow-up times than do Phase I trials. Within Phase II trials, participants are closely monitored for safety. In addition, pharmacokinetic, pharmacodynamic, or pharmacogenomic studies or a combination are often incorporated as part of the Phase II trial design. In many settings, two or more Phase II trials are undertaken prior to a Phase III trial.

Phase III trials are undertaken if the Phase II trial or trials demonstrate that the drug may be reasonably safe and potentially effective. The primary goal of a Phase III trial is to compare the effectiveness of the new treatment with that of either a placebo condition or standard of care. Phase III trials may involve long-term follow-up and many participants. The sample size is determined using precise statistical methods based on the end point of interest, the clinically relevant difference between treatment arms, and control of Type I and Type II error rates. The FDA may require two Phase III trials for approval of new drugs. The process from drug synthesis to the completion of a Phase III trial may take several years. Many investigations may never reach the Phase II or Phase III trial stage.

The gold-standard design in Phase III trials employs randomization and is double blind. That is, participants who are enrolled in the study agree to have their treatment selected by a random or pseudorandom process, and neither the evaluator nor the participants have knowledge of the true treatment assignment. Appropriate randomization procedures ensure that the assigned treatment is independent of any known or unknown prognostic characteristic. Randomization provides two important advantages. First, the treatment groups tend to be comparable with regard to prognostic factors. Second, it provides the theoretical underpinning for a valid statistical test of the null hypothesis. Randomization and blinding are mechanisms used to minimize potential bias that may arise from multiple sources. Oftentimes blinding is impossible or infeasible due to either safety issues or more obvious reasons such as the clear side effects of the active regimen compared with a placebo control group. Randomization cannot eliminate statistical bias due to issues such as differential dropout rates, differential noncompliance rates, or any other systematic differences imposed during the conduct of a trial.

Phase IV clinical trials are oftentimes referred to as postmarketing studies and are generally surveillance studies conducted to evaluate long-term safety and efficacy within the new patient population.

Nonrandomized Clinical Trials

In nonrandomized observational studies, there is no attempt to intervene in the participants' selection

between the new and the standard treatments. When the results of participants who received the new treatment are compared with the results of a group of previously treated individuals, the study is considered historically controlled. Historically controlled trials are susceptible to several sources of bias, including those due to shifts in medical practice over time, changes in response definitions, and differences in follow-up procedures or recording methods. Some of these biases can be controlled by implementing a parallel treatment design. In this case, the new and the standard treatment are applied to each group of participants concurrently. This approach provides an opportunity to standardize the participant care and evaluation procedures used in each treatment group. The principal drawback of observational trials (historically controlled or parallel treatment) is that the apparent differences in outcome between the treatment groups may actually be due to imbalances in known and unknown prognostic subject characteristics. These differences in outcome can be erroneously attributed to the treatment, and thus these types of trials cannot establish a cause-and-effect relationship.

Screening Trials

Screening trials are conducted to determine whether preclinical signs of a disease should be monitored to increase the chance of detecting individuals with curable forms of the disease. In these trials there are actually two interventions. The first intervention is the program of monitoring normal individuals for curable forms of disease. The second intervention is the potentially curative procedure applied to the diseased, detected individuals. Both these components need to be effective for a successful screening trial.

Prevention Trials

Prevention trials evaluate interventions intended to reduce the risk of developing a disease. The intervention may consist of a vaccine, high-risk behavior modification, or dietary supplement.

Ethics in Clinical Trials

The U.S. Research Act of 1974 established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The purpose of this commission was to establish ethical guidelines for clinical research. The act also mandated that all clinical trials funded entirely or in part by the federal government be reviewed by IRBs. The commission outlined in detail how IRBs should function and provided ethical

guidelines for conducting research involving human participants. The commission's Belmont Report articulated three important ethical principles for clinical research: respect for persons, beneficence, and justice.

The principle of respect for persons acknowledges that participants involved in clinical trials must be properly informed and always permitted to exercise their right to self-determination. The informed consent process arises from this principle. The principle of beneficence acknowledges that there is often a potential for benefit as well as harm for individuals involved in clinical trials. This principle requires that there be a favorable balance toward benefit, and any potential for harm must be minimized and justified. The principle of justice requires that the burdens and benefits of clinical research be distributed fairly. An injustice occurs when one group in society bears a disproportionate burden of research while another reaps a disproportionate share of its benefit.

CLUSTER ANALYSIS

Cluster analysis is the means by which investigators classify targets of measurement or cases such as people, products, or places into meaningful groups or types using a set of predefined characteristics. This collection of multivariate techniques uses investigator-determined criteria to assemble measurement targets into clusters that simultaneously convey high within-cluster homogeneity and high between-cluster heterogeneity. A large number of observations can be classified into

manageable units, and patterns, taxonomies, or collections of symptoms may be reasonably detected when cluster analysis is used accurately. Such classifications help investigators understand how members of particular subsets resemble one another and differ from members of other subsets within and across samples.

Imagine, for example, the task of classifying students according to their abilities and interests so that instruction may be more easily targeted to the needs of each subgroup. Teachers could define and measure specific talents and tastes and use cluster analysis to add parsimony to this complex set of measurements. Whereas other multivariate statistical techniques rely on decontextualized, empirical estimates of the variate used in analyses, cluster analysis requires the investigator, in this case the teacher, to determine which set of variables to incorporate into the *cluster variate* that is used in the classification process. If done well, cluster analysis would allow this teacher to classify students with similar interests and abilities into the same cluster and those with different interests and abilities into alternate clusters.

The remainder of this entry describes when to use cluster analysis, examines in detail the steps involved in cluster analysis, and concludes by highlighting subsets and commonalities in evidence from cluster analyses.

When to Use Cluster Analysis

Cluster analysis can be used for many different purposes. In the field of family psychology, for example, cluster analysis has been used to derive family types, study families over time, integrate data emerging from multiple methods, explore nonlinear models, and reduce data complexity in small samples. Cluster analysis is useful when investigators want to understand the subgroups within their sample because this technique offers nonlinear heuristics for comparing members of a sample with one another. This collection of multivariate processes is ideal when investigators want to define and explore different patterns of variance within a data set or compare the emergence of such patterns across data sets.

A few cautions should be considered when employing cluster analysis. First, the evidence generated from cluster analysis is sample-dependent such that findings may not be readily generalizable to larger populations. In many situations, this is a benefit of the approach, but it is important to remember that any obtained results reflect descriptive, noninferential depictions of the data selected for the cluster variate.

Cluster solutions are not ideal for testing specific hypotheses, making enduring diagnoses, or confirming

the existence of general theoretical structures because they offer, at best, an exploratory description of the data used to generate them. This means that when statistical tests are used as part of the cluster analysis process, they serve only to verify that the generated clusters are indeed sufficiently different from one another. Such analyses do not validate claims about the names or qualities of any identified clusters.

A second consideration involves whether clusters actually exist in the data set. Because cluster analysis compares measurement targets to determine their relative similarity and difference, the resulting clusters cannot be declared “meaningful” without being interpreted by the investigator. Computer algorithms produce multiple cluster solutions, and any clumping may essentially be random. The extent to which data distributions are truly aggregated, systematically regular, or randomly distributed yields greater and lesser degrees of clustering. Thus, external logic is essential to the process of validating cluster choices.

A third consideration is the fact that cluster analysis can yield different conclusions when applied to a single data set. Solutions may differ because a number of factors, many of which are determined by investigators, are likely to affect the results. For example, including different scores or variables in a cluster analysis will result in different classifications. The decisions used to build a cluster variate and for determining what linkage methods to use when comparing cases will influence the results. Likewise, implementation decisions about how to compare the targets of each measurement to one another will influence the results. Generally speaking, implementation decisions focus on how similarity is defined, the rules used for comparing observations, and how many clusters or groups are to be formed.

Investigators have been comparing different clustering procedures well enough to offer advice on how to use multiple existing and emerging methods, in combination, to address problematic issues and increase confidence in the appropriateness of cluster analysis for specific uses. Solutions from a range of different analytical approaches are often compared to explore how the results differ. When classifications remain the same, regardless of the analytical strategy, confidence in how the solutions are interpreted can be better than when cases are situated differently across approaches.

When making procedural decisions, it is helpful to ask why cluster analysis is appropriate. Across disciplines, cluster analysis has been used to identify taxonomies, facilitate data reduction, and identify relationships between the ideas embodied in clusters and characteristics that are not part of these clusters

with greater levels of discrimination. Data sets have been employed to explore the existence of typologies or to confirm theoretically generated descriptions. As a data reduction technique, cluster analysis has allowed investigators to simplify features of a more complex statistical story well enough to answer complex research questions. Additionally, cluster analysis has been used as a means of creating stronger independent variables for use in more complex analyses.

Steps in Cluster Analysis

Answers to questions about why cluster analysis is appropriate allow investigators to make a host of decisions. The parameters of specific purposes offer structure to the decision-making process.

Choosing What to Cluster

The first, and perhaps most important, step in cluster analysis is the selection of theoretically driven measures and sample parameters. Although cluster analysis has strong mathematical properties, it has no statistical foundation. Thus, the typical normality, linearity, and homoscedasticity assumptions associated with many multivariate approaches have little bearing. Nevertheless, three critical issues must be addressed before cluster analyses can be valid. First, choosing which data sources to include in cluster variates affects the interpretation of any results. Second, cluster analysis is only as good as the representativeness of the sample. Additionally, multicollinearity acts as an implicit weighting process in cluster analysis in a way that might not be detected by an investigator. All three priorities highlight the challenges associated with maximizing the discriminating power of cluster analysis while minimizing redundancies. Cluster solutions can be valid with a representative sample and by aggregating highly similar scores before conducting the analysis to better distinguish subgroups within a data set.

Valid data analysis requires equitable scaling so that variables are weighted in a theoretically meaningful manner. One of the simplest approaches to standardization is to divide each variable by its respective range, building a common metric that maintains variance in the raw data. Variables can also be standardized using common *normalized distance functions* (e.g., *z-scores*) to create a common metric for each characteristic of the intended cluster variate. Another option is to standardize scores by the target of measurement or case, mitigating possible response-style biases by using within-case standardization. Each approach to standardization has strengths and limitations in terms of their overall effect on the final solutions.

Verifying the Existence of Clusters

Another initial question focuses on whether it is even reasonable to subdivide the targets of measurement into clusters. Investigators often begin by visually examining data distributions and considering the extent to which data appear to be clustered. They look for higher and lower densities in how cases are grouped after creating cluster variates. Decisions about how to define similarity are central to this step. Similarity may be defined as *correlations* when the magnitude of the relations is irrelevant to decisions about how to use the solution. Measures of *distance* are typically used when the magnitude of the values and their proximity to one another matter to the investigator: Cases with lower distances show greater similarity. Similarity is also defined using *associational measures* such as the percent of agreement or other matching indices when the characteristics being measured have nominal or ordinal properties.

Before deciding to create clusters, investigators also look for *entropy groups* or outlying cases. Highly unusual cases are likely to distort the effectiveness of any algorithms used to build clusters. Relying on theory and practical reasons for creating subgroups, investigators decide whether to remove outliers, recalibrate the content of cluster variates, or use another definition of similarity in their analyses.

Choosing a Clustering Algorithm

Assuming that cluster analysis will be worthwhile, investigators choose a clustering algorithm or means of comparing cases and cluster variates. Classes of cluster algorithms include hierarchical, nonhierarchical, and overlapping or associational methods. Hierarchical methods are most commonly applied because they can detect both nested and non-nested structures while taking advantage of variance in interval or ratio data. Nonhierarchical approaches also operate using continuous data but assume mutually exclusive categories, without nesting. Overlapping or associational algorithms are useful for categorical data and procedures are currently being devised and tested in multiple contexts.

Hierarchical Algorithms

Hierarchical methods join or link cases into clusters by following one of two types of procedures. *Agglomerative procedures* start by treating each case as a separate cluster and systematically grouping those with similar cluster variates into more complex clusters. As clusters are formed, they are joined with other clusters using distance metrics. *Distance metrics* express the

distances between cases in multivariate space. Decisions about which metric to use are implemented to create larger clusters until all observations are joined in a single cluster. *Divisive procedures* start from the reverse direction, treating all cases as if they are members of the same cluster and subdividing these cases using specified distance metrics. Currently, most computer programs rely on agglomerative procedures using distance metrics to identify clusters of similar cases.

The most commonly used distance metric, Euclidian distance, is calculated by summing the squared differences between cases on each variable that comprises the cluster variate, and using the square root of that sum. Removing the square root from that equation generates a squared Euclidian distance that is sometimes recommended for some of the more complex methods of defining similarity. Correlations and associational scores are used less often but may also convey relative distance.

Various linking algorithms are used to join cases when building clusters. *Linkage* is the point within any cluster from which distance measures will be calculated. Linkage decisions may focus on the most distant case in each cluster as it compares with cases outside the cluster, the closest case, or an average of distance scores for cases in each cluster. *Single linkage*, for example, starts with the smallest distance between observations in any two clusters and is sometimes called the *nearest neighbor*. *Complete linkage* starts with the greatest distance between observations, the farthest neighbor. *Average linkage* starts with either single or complete linkage, but then compares the average distances between cases in one cluster with the average distance between cases in the others. *Centroid linkage* relies on cluster centroids, the mean values of observations on the variables in the cluster variate; centroids are calculated for each cluster as they are formed and reformed in subsequent steps of the analysis. Additionally, *Ward's linkage* method uses the degree of similarity between observations in the same cluster to minimize the within-cluster sum of squares to link cases across the analyses. In short, distance metrics and linkage decisions are two features of hierarchical algorithms that may be selected by investigators.

Nonhierarchical Algorithms

Nonhierarchical procedures identify discrete clusters by specifying the number of clusters to be extracted. A cluster seed is used to define the initial cluster center, and all targets or cases are aligned using a prespecified threshold distance from this seed. As this process is repeated for other alternative seeds, cases are assigned and reassigned to the cluster whose center is nearest,

simultaneously adjusting the initial centers and the classification of cases. This process continues until no cases change their cluster membership. Scree plots or t tests and F tests can be used to compare the distances between individual cases and their cluster centers.

Often known as *K-means* clustering, nonhierarchical algorithms may produce different results depending on how cases are initially positioned. Three examples of how seeds are selected potentially yield distinctly different cluster assignments, but using theoretical, practical, and/or objective criteria to make such selections can yield valid results. *Parallel threshold methods* simultaneously assign cases within a specified threshold distance to the nearest seed. *Sequential threshold methods* start with one seed, and cases are assigned with a prespecified distance to that seed before selecting a second seed. This sequential process is repeated by considering only the unclassified cases as subsequent clusters are formulated. *Optimization procedures* allow for the reassignment of clusters as well as cases when a case becomes too close to a new cluster.

Depending on computer programming decisions, the order of cases in a data set can control the nature and structure of clusters generated using nonhierarchical algorithms. Nonhierarchical algorithms can also be less flexible in how distance metrics and linkage approaches are chosen. Nevertheless, these algorithms allow cluster centers to be entered by the investigator or chosen at random by the program.

Comparing Findings From Multiple Approaches

Given the limitations of each class of algorithms, many investigators compare the solutions generated using different procedures before settling on their final solution. Nonhierarchical algorithms, for example, are often used as a second step, following hierarchical clustering and theoretical discussions to determine how many clusters to expect. Findings from exploratory analyses allow investigators to make informed choices about where to place the initial cluster centers, and cases are assigned to clusters by relying on the benefits of nonhierarchical approaches.

Interpreting the Cluster Solution

Interpreting and comparing different cluster solutions is one of the most complex steps of cluster analysis. Determining the number of clusters to be interpreted is as much a theoretical process as it is empirical. Strict empirical judgments are ideally complemented with theoretical propositions and investigators watch for conceptual problems such as single-member clusters and/or overpopulated clusters. Seeking parsimony and

practicality, they formulate stopping rules such as criteria for a minimum acceptable distance between clusters or limits on the average similarity within and across clusters. Decisions can also be made by looking for sudden changes in the overall distribution of cluster distances.

The nature of the distances between solutions is another consideration that is best illustrated using different methods of plotting cluster patterns. David B. Henry and colleagues (2005) recommended using radar plots, start plots, or sun ray plots to examine the qualities of complex solutions.

Naming the distinctive features of each cluster and aligning those features with the content of the information in each cluster variate can help investigators align theoretical and empirical information. Post hoc comparison of all combinations of cluster means may be conducted by saving the cluster membership identifier for each case and using that classification as an independent variable in analysis of variance to explore how raw data differ across clusters. These suggestions reflect but a sample of possible comparisons made when interpreting cluster solutions.

Validating Cluster Solutions

Validity focuses on how well a selected solution offers generalizable support for theoretical claims. The importance of attending to content validity in every step of cluster analysis cannot be overstated if solutions are to be valid. Additionally, conclusions are commonly validated by reanalyzing data using different clustering algorithms or decisions. When samples are large enough to split or when a second sample is available, repeating procedures on different data sets adds validity support. Additionally, procedures commonly used to explore predictive, criterion, and construct validity are also important aspects of strengthening validity claims about cluster solutions.

Subsets and Commonalities in Evidence

Cluster analysis is underutilized as a means of identifying complex independent variables that may otherwise be invisible to observers. Likewise, investigators may not want to generate universal taxonomies, preferring instead to offer nuanced descriptions of complex constructs or contexts. As investigators recognize their responsibilities for examining the qualities of the data they collect, they may come to appreciate the power of this approach for detecting truth and bias in their research. Comparing approaches used by scholars from different disciplines may further assist those who are

developing reliable and valid analytical algorithms for classifying people, places, and things.

CLUSTER SAMPLING

A variety of sampling strategies are available in cases when setting or context create restrictions. For example, *stratified sampling* is used when the population’s characteristics such as ethnicity or gender are related to the outcome or dependent variables being studied. *Simple random sampling*, in contrast, is used when there is no regard for strata or defining characteristics of the population from which the sample is drawn. The assumption

is that the differences in these characteristics are normally distributed across all potential participants.

Cluster sampling is the selection of units of natural groupings rather than individuals. For example, in marketing research, the question at hand might be how adolescents react to a particular brand of chewing gum. The researcher may access such a population through traditional channels such as the high school but may also visit places where these potential participants tend to spend time together, such as shopping malls and movie theaters. Rather than counting each one of the adolescents’ responses to a survey as one data point, the researcher would count the entire group’s average as the data point. The assumption is that the group data point is a small representative of the population of all adolescents. The fact that the collection of individuals in the unit serves as the data point, rather than each individual serving as a data point, differentiates this sampling technique from most others.

An advantage of cluster sampling is that it is a great time saver and relatively efficient in that travel time and other expenses are saved. The primary disadvantage is that one can lose the heterogeneity that exists within groups by taking all in the group as a single unit; in other words, the strategy may introduce sampling error. Cluster sampling is also known as *geographical sampling* because areas such as neighborhoods become the unit of analysis.

An example of cluster sampling can be seen in a study by Michael Burton from the University of California and his colleagues, who used both stratified and cluster sampling to draw a sample from the U.S. Census archives for California in 1880. These researchers emphasized that with little effort and expended resources, they obtained very useful knowledge about California in 1880 pertaining to marriage patterns, migration patterns, occupational status, and categories of ethnicity. Another example is a study by Lawrence T. Lam and L. Yang of duration of sleep and attention-deficit/hyperactivity disorder among adolescents in China. The researchers used a variant of simple cluster sampling, two-stage random cluster sampling design, to assess duration of sleep.

While cluster sampling may not be the first choice given all options, it can be a highly targeted sampling method when resources are limited and sampling error is not a significant concern.

COCHRAN–ARMITAGE TEST FOR TREND

The Cochran–Armitage (CA) test for trend, named for William Cochran and Peter Armitage, is used in categorical data analysis when the aim is to evaluate the existence of a relationship between a two-category variable and an ordered variables with k categories. It modifies the Pearson chi-square test to include a questionable ranking to the effects of the k categories of the second variable. For example, the doses of a treatment can be ordered as “low,” “medium,” and “high,” and we may suspect that the treatment benefit will not decrease as the dose increases.

Trend testing is often used as a genotype-based test for case-controlled genetic association studies. In biological research, for example, $2 \times C$ size contingency tables are frequently used for the analysis of ordered categorical data. A $2 \times C$ table has any number of groups (C = number of groups) with 2 possible scores or categories for members of each group. With the CA test for trend, C groups can be ordered as normal, moderately normal, and abnormal, and 1, 2, and 3 can be assigned to them, respectively, as scores. Likewise, in a study, ordinal numbers can have a real number value or a score value as the daily dosage of a substance.

D. G. Chapman and Jun-mo Nam (1968) stated that the test is similar, but not exactly the same as, tests of noncentral distributions. The power of this test is a function of the sample sizes of the groups and the positive rates between the groups. Nam (1987) presented the power of the CA test as a function of the linear trend of logit probabilities. S. L. Slager and D. J. Schaid (2001) have shown that the power of the CA test, under the null hypothesis and alternative hypotheses, corresponds to the Z-test.

This entry discusses the use of the CA test for testing the linear trend both in increasing and decreasing

proportions. It also considers the planning a research design that utilizes the CA test.

The CA Test

This CA trend tests trends in binomial ratios at the levels of a single variable. This test is only suitable when a variable has two levels and the other variable is ordered. The two-level variable represents the response, while the other represents an explanatory variable with ordered levels. The null hypothesis is the no-trend hypothesis; this means that the binomial rate is the same for all levels of the explanatory variable.

A central goal of genome-wide association studies (GWAS) is to identify genetic risk factors for complex disorders. To find the disease genetic risk factors in a population, GWAS measures DNA sequence variations across human genome. The association tests are performed separately for each individual marker and depending on the aim of study, the data for each marker with minor allele a and major allele A can be represented either as genotype count (e.g., a/a , A/a and A/A) or allele count (e.g., a and A). It is widely believed that the allelic association test with 1 degree of freedom (df) is more reliable than the genotypic test with 2 df . However, this superior performance can only be considered for the case of having the penetrance of the heterozygote genotype between the penetrance of the two homozygote genotypes. When the distribution of genotypes in the population deviates from Hardy–Weinberg proportions (HWE), of which additive, dominant, and recessive models are all examples, the frequency of genotypes rather than alleles should be compared by the CA test for trend.

Thus, the advantage of the CA trend test in comparison to Pearson’s chi-square test is that it possesses the superior conservation and is not dependent on the HWE assumption. Therefore, authors have recommended to use the CA trend test as the genotype-based test for association. It should be noted that the allelic and trend statistic are equivalent when the combined sample is in HWE.

The sample size and the power of the CA test are calculated based on the results of Nam (1987). There are asymptotic power and exact power calculations for noncorrected tests and correction for continuity tests. As X was a covariate (or doses), it was assumed to follow a linear trend with a logistic measure, and random samples were extracted from k different populations.

It is assumed that there are k random binomial variables y_i , refers to factor or dose levels; x_i , n_i refers to sample sizes and p_i refers to the probability of success. For $i = 1, 2, \dots, k$ and when $x_1 < x_2 < \dots < x_k$, it is defined as follows:

$$N = \sum_{i=1}^k n_i \quad \bar{p} = \frac{1}{N} \sum_{i=1}^k y_i \quad (1)$$

$$\bar{x} = \frac{1}{N} \sum_{i=1}^k n_i x_i \quad \bar{q} = 1 - \bar{p}. \quad (2)$$

Equation 3 is used if it is assumed that success rates follow a linear trend with a logistic scale.

$$p_i = \frac{\exp(\alpha + \beta x_i)}{1 + \exp(\alpha + \beta x_i)} \quad (3)$$

The One-Sided Testing of the Linear Trend Increasing in Proportions

In this subsection, the correction for continuity test statistic and the noncorrected test statistic for the one-sided testing of the linear trend increasing in proportions are presented. The trend option in the tables statement requests the CA test for trend, which tests for trend in binomial proportions across levels of a single factor or covariate. This test is appropriate for a contingency table in which one variable has two levels and the other variable is ordinal. The two-level variable represents the response, and the other variable represents an explanatory variable with ordered levels. There are two different notations for correction for continuity test and noncorrected test.

Correction for Continuity Test

Nam (1987) recommended the following asymptotic correction for continuity test statistic for the one-sided testing of the linear trend increasing in proportions.

$$Z_{c.c.} = \frac{\sum_{i=1}^k y_i (x_i - \bar{x}) - \frac{\Delta}{2}}{\sqrt{\bar{p}\bar{q} \left[\sum_{i=1}^k n_i (x_i - \bar{x})^2 \right]}} \quad (4)$$

Correction factor for continuity is $\frac{\Delta}{2}$. If the covariate is x_i , it can consist of even spaces or successive spaces.

$$\Delta = x_{i+1} - x_i \quad i < k \quad (5)$$

For unevenly spaced covariates, Δ is calculated as follows:

$$\Delta = \frac{1}{k-1} \sum_{i=1}^{k-1} (x_{i+1} - x_i). \quad (6)$$

Continuity for correction was not recommended for the covariates divided into uneven spaces. Thus, a noncorrected test must be used in case of the presence of factors divided into unequal spaces.

Noncorrected Test

The noncorrected test statistic is the $\Delta = 0$ version of the corrected test statistic.

$$Z = \frac{\sum_{i=1}^k y_i (x_i - \bar{x})}{\sqrt{\bar{p}\bar{q} \left[\sum_{i=1}^k n_i (x_i - \bar{x})^2 \right]}} \quad (7)$$

The One-Sided Testing of the Linear Trend Decreasing in Proportions

CA tests for trend in binomial proportions across the levels of a single variable. This test is appropriate only when one variable has two levels and the other variable is ordinal. The two-level variable represents the response, and the other represents an explanatory variable with ordered levels. The null hypothesis is the hypothesis of no trend, which means that the binomial proportion is the same for all levels of the explanatory variable. There are two different notations for correction for continuity test and noncorrected test. This subsections explain the correction for the continuity test statistic and the noncorrected test statistic for one-sided testing of the linear trend decreasing in population.

Correction for Continuity Test

Nam (1987) found the asymptotic correction for continuity test statistic for the one-sided testing of the linear trend increasing in proportions. The correction for continuity test is calculated for the one-sided testing of the linear trend decreasing in proportions in the same way. However, here, $\frac{\Delta}{2}$ factor is added, but not subtracted.

$$Z_{c.c.} = \frac{\sum_{i=1}^k y_i (x_i - \bar{x}) + \frac{\Delta}{2}}{\sqrt{\bar{p}\bar{q} \left[\sum_{i=1}^k n_i (x_i - \bar{x})^2 \right]}} \quad (8)$$

Noncorrected Test

The noncorrected test statistic is the $\Delta = 0$ version of the corrected test statistic.

$$Z = \frac{\sum_{i=1}^k y_i (x_i - \bar{x})}{\sqrt{\bar{p}\bar{q} \left[\sum_{i=1}^k n_i (x_i - \bar{x})^2 \right]}} \quad (9)$$

The CA Trend Test Approximate Power Calculation

In this subsection, the approximate power calculations for testing linear trends are described. An asymptotic test of significance of linear trend in proportions is given by Cochran (1954) and Armitage (1955). This test is known to be more powerful than the chi-square homogeneity test in identifying a trend. Approximate formulas for calculating sample sizes for comparing two independent binomial proportions have been studied by many investigators. In this, such an explicit formula for sample sizes is derived for the asymptotic power function of the one-sided CA test. The proposed approximation is computationally simple and is useful in experimental design.

Power for the One-Sided Testing of the Linear Trend Increasing in Proportions

The critical value z_{critical} is found by use of the standard normal distribution. For the one-sided testing of the alternative hypothesis, p_i is a monotonically increasing function of x_i . For $p = (p_1, p_2, \dots, p_k)$, power is calculated according to Equation 10.

$$1 - \beta = \Pr(z \geq z_{\text{critical}} | H_1) \\ = 1 - \Phi(u_U) \quad (10)$$

In Equation 10, “ Φ ” indicates cumulative normal distribution.

$$u_U = \frac{-\left[\sum_{i=1}^k n_i p_i (x_i - \bar{x}) - \frac{\Delta}{2}\right] + z_{\text{critical}} \sqrt{p(1-p) \sum_{i=1}^k n_i (x_i - \bar{x})^2}}{\sqrt{\sum_{i=1}^k n_i p_i (1-p_i) (x_i - \bar{x})^2}} \quad (11)$$

$$p = \frac{1}{N} \sum_{i=1}^k n_i p_i \quad (12)$$

While power is being calculated for the noncorrected test, it is assumed that $\Delta = 0$.

Power for the One-Sided Testing of the Linear Trend Decreasing in Proportions

The critical value z_{critical} is founded by use of the standard normal distribution. For the one-sided testing of the alternative hypothesis, p_i is a monotonically decreasing function of x_i . For $p = (p_1, p_2, \dots, p_k)$, power is calculated according to Equation 13.

$$1 - \beta = \Pr(z \leq -z_{\text{critical}} | H_1) \\ = 1 - \Phi(u_L) \quad (13)$$

Here, “ Φ ” is cumulative normal distribution.

$$u_U = \frac{-\left[\sum_{i=1}^k n_i p_i (x_i - \bar{x}) + \frac{\Delta}{2}\right] + z_{\text{critical}} \sqrt{p(1-p) \sum_{i=1}^k n_i (x_i - \bar{x})^2}}{\sqrt{\sum_{i=1}^k n_i p_i (1-p_i) (x_i - \bar{x})^2}} \quad (14)$$

$$p = \frac{1}{N} \sum_{i=1}^k n_i p_i \quad (15)$$

In medical applications, where categorical variables are widespread, ordinal variables in particular can often be meaningfully structured into sets. Examples include questions in psychomedical diagnostic tests (e.g., structured into sets by the subdimension they describe), side effects in drug safety studies (e.g., structured into sets by the body function they affect), items in questionnaire based studies on functional limitations and disabilities (e.g., structured into sets by means of the International Classification of Functioning, Disability and Health), and single nucleotide polymorphisms in next generation sequencing studies (e.g., structured into sets by genes). Typically, such prior knowledge is not exploited inferentially, and one simply performs well established univariate tests for each variable.

When the objective is to assess the presence of an association with some binary variable, for example, the most widely used univariate test for ordinal variables is the two-sided CA test for trend Equations 3 and 4, which, in medical statistics, is usually better known as the one-sided formulation of Equation 8. As with gene expression data, however, in the case of ordinal data it may likewise be preferable to shift the unit of analysis from individual variables to whole sets of variables.

Planning a Research Design Using the CA Test

The stages of a research are as follows: formulating hypotheses, research design, data collection, and statistical analysis. Statistical analysis is the stage before the classic presentation of the research results. This stage involves the interpretation of the test results based on statistical significance. On one hand, just like statistical significance does not give any information about the content of the analyzed data, it may also be found significant just because of the largeness of the sample size in some cases. On the other hand, a statistically insignificant result may result from the smallness of the sample size or taking random variables from a sample that does not represent the related group. In other words, the results may have been found statistically significant or statistically insignificant wrongly. Because working with a very large sample may lead to loss of

time, labor, and money, appropriate sample size must be determined within the framework of research hypothesis and research purpose in the planning stage of the study.

In biological and medical research, determination of sample size is an important part of scientific research process. On one hand, in a study where the sample size is much larger than necessary, the researcher will achieve his or her purpose before the study ends, and so some experimental units will have been included in the study unnecessarily. On one hand, when the sample size is much smaller than necessary, it will be less likely for the researcher to achieve his or her purpose. Accordingly, in a biological research, sample size must allow the addressed hypotheses to be tested reliably.

A test commonly used to determine whether a dose-response relationship exists in a wide variety of biomedical settings, including clinical trials, carcinogenicity studies, central goal of GWAS, and toxicological risk assessment, is the CA test for trend. Data from such studies are represented as ordered contingency tables. Modern algorithmic techniques (Mehta, Patel, & Senchaudhuri, 1992) and software (e.g., StatXact) facilitate computing an exact CA p value guaranteed to preserve the Type 1 error, even if these contingency tables have many small or zero cell counts.

“COEFFICIENT ALPHA AND THE INTERNAL STRUCTURE OF TESTS”

Lee Cronbach's 1951 *Psychometrika* article “Coefficient Alpha and the Internal Structure of Tests” established coefficient alpha as the preeminent estimate of internal consistency reliability. Cronbach demonstrated that coefficient alpha is the mean of all split-half reliability coefficients and discussed the manner in which coefficient alpha should be interpreted. Specifically, alpha estimates the correlation between two randomly parallel tests administered at the same time and drawn from a universe of items like those in the original test. Further, Cronbach showed that alpha does not require the assumption that items be unidimensional. In his reflections 50 years later, Cronbach described how

coefficient alpha fits within *generalizability theory*, which may be employed to obtain more informative explanations of test score variance.

Concerns about the accuracy of test scores are commonly addressed by computing *reliability coefficients*. An *internal consistency reliability coefficient*, which may be obtained from a single test administration, estimates the consistency of scores on repeated test administrations taking place at the same time (i.e., no changes in examinees from one test to the next). *Split-half reliability coefficients*, which estimate internal consistency reliability, were established as a standard of practice for much of the early 20th century, but such coefficients are not unique because they depend on particular splits of items into half tests. Cronbach presented coefficient alpha as an alternative method for estimating internal consistency reliability. Alpha is computed as follows:

$$\frac{k}{k-1} \left(1 - \frac{\sum_i s_i^2}{s_t^2} \right),$$

where k is the number of items, s_i^2 is the variance of scores on item i , and s_t^2 is the variance of total test scores. As demonstrated by Cronbach, alpha is the mean of all possible split-half coefficients for a test. Alpha is generally applicable for studying measurement consistency whenever data include multiple observations of individuals (e.g., item scores, ratings from multiple judges, stability of performance over multiple trials). Cronbach showed that the well-known Kuder–Richardson formula 20 (KR-20), which preceded alpha, was a special case of alpha when items are scored dichotomously.

One sort of internal consistency reliability coefficient, the *coefficient of precision*, estimates the correlation between a test and a hypothetical replicated administration of the same test when no changes in the examinees have occurred. In contrast, Cronbach explained that alpha, which estimates the *coefficient of equivalence*, reflects the correlation between two different k -item tests randomly drawn (without replacement) from a universe of items like those in the test and administered simultaneously. Since the correlation of a test with itself would be higher than the correlation between different tests drawn randomly from a pool, alpha provides a lower bound for the coefficient of precision. Note that alpha (and other internal consistency reliability coefficients) provides no information about variation in test scores that could occur if repeated testings were separated in time. Thus, some have argued that such coefficients overstate reliability.

Cronbach dismissed the notion that alpha requires the assumption of item unidimensionality (i.e., all items measure the same aspect of individual

differences). Instead, alpha provides an estimate (lower bound) of the proportion of variance in test scores attributable to all common factors accounting for item responses. Thus, alpha can reasonably be applied to tests typically administered in educational settings and that comprise items that call on several skills or aspects of understanding in different combinations across items. Coefficient alpha, then, climaxed 50 years of work on correlational conceptions of reliability begun by Charles Spearman.

In a 2004 article published posthumously, “My Current Thoughts on Coefficient Alpha and Successor Procedures,” Cronbach expressed doubt that coefficient alpha was the best way of judging reliability. It covered only a small part of the range of measurement uses, and consequently it should be viewed within a much larger system of reliability analysis, generalizability theory. Moreover, alpha focused attention on reliability coefficients when that attention should instead be cast on measurement error and the standard error of measurement.

For Cronbach, the extension of alpha (and classical test theory) came when Fisherian notions of experimental design and analysis of variance were put together with the idea that some “treatment” conditions could be considered random samples from a large universe, as alpha assumes about item sampling. Measurement data, then, could be collected in complex designs with multiple variables (e.g., items, occasions, and rater effects) and analyzed with random-effects analysis of variance models. The goal was not so much to estimate a reliability coefficient as to estimate the components of variance that arose from multiple variables and their interactions in order to account for observed score variance. This approach of partitioning effects into their variance components provides information as to the magnitude of each of the multiple sources of error and a standard error of measurement, as well as an “alpha-like” reliability coefficient for complex measurement designs. Moreover, the variance-component approach can provide the value of “alpha” expected by increasing or decreasing the number of items (or raters or occasions) like those in the test. In addition, the proportion of observed score variance attributable to variance in item difficulty (or, for example, rater stringency) may also be computed, which is especially important to contemporary testing programs that seek to determine whether examinees have achieved an absolute, rather than relative, level of proficiency. Once these possibilities were envisioned, coefficient alpha morphed into generalizability theory, with sophisticated analyses involving crossed and nested designs with random and fixed variables (*facets*) producing variance components for multiple measurement

facets such as raters and testing occasions so as to provide a complex standard error of measurement.

By all accounts, coefficient alpha—Cronbach's alpha—has been and will continue to be the most popular method for estimating behavioral measurement reliability. As of 2004, the 1951 coefficient alpha article had been cited in more than 5,000 publications.

COEFFICIENT OF VARIATION

The coefficient of variation measures the variability of a series of numbers independent of the unit of measurement used for these numbers. In order to do so, the coefficient of variation eliminates the unit of measurement of the standard deviation of a series of numbers by dividing the standard deviation by the mean of these numbers. The coefficient of variation can be used to compare distributions obtained with different units, such as the variability of the weights of newborns (measured in grams) with the size of adults (measured in centimeters). The coefficient of variation is meaningful only for measurements with a real zero (i.e., "ratio scales") because the mean is meaningful (i.e., unique) only for these scales. So, for example, it would be meaningless to compute the coefficient of variation of the temperature measured in degrees Fahrenheit, because changing the measurement to degrees Celsius will not change the temperature but will change the value of the coefficient of variation (because the value of zero for Celsius is 32 for Fahrenheit, and therefore

the mean of the temperature will change from one scale to the other). In addition, the values of the measurement used to compute the coefficient of variation are assumed to be always positive or null. The coefficient of variation is primarily a descriptive statistic, but it is amenable to statistical inferences such as null hypothesis testing or confidence intervals. Standard procedures are often very dependent on the normality assumption, and current work is exploring alternative procedures that are less dependent on this normality assumption.

Definition and Notation

The coefficient of variation, denoted C_v (or occasionally V), eliminates the unit of measurement from the standard deviation of a series of numbers by dividing it by the mean of this series of numbers. Formally, if, for a series of N numbers, the standard deviation and the mean are denoted respectively by S and M , the coefficient of variation is computed as

$$C_v = \frac{S}{M}. \quad (1)$$

Often the coefficient of variation is expressed as a percentage, which corresponds to the following formula for the coefficient of variation:

$$C_v = \frac{S \times 100}{M}. \quad (2)$$

This last formula can be potentially misleading because, as shown later, the value of the coefficient of variation can exceed 1 and therefore would create percentages larger than 100. In that case, Equation 1, which expresses C_v as a ratio rather than a percentage, should be used.

Range

In a finite sample of N nonnegative numbers with a real zero, the coefficient of variation can take a value between 0 and $\sqrt{N-1}$ (the maximum value of C_v is reached when all values but one are equal to zero).

Estimation of a Population Coefficient of Variation

The coefficient of variation computed on a sample is a *biased* estimate of the population coefficient of variation denoted γ_v . An unbiased estimate of the

population coefficient of variation, denoted $\hat{C}_v$, is computed as

$$\hat{C}_v = \left(1 + \frac{1}{4N}\right) C_v \quad (3)$$

(where N is the sample size).

Testing the Coefficient of Variation

When the coefficient of variation is computed on a sample drawn from a normal population, its standard error, denoted σ_{C_v} , is known and is equal to

$$\sigma_{C_v} = \frac{\gamma_v}{\sqrt{2N}} \quad (4)$$

When γ_v is not known (which is, in general, the case), σ_{C_v} can be estimated by replacing γ_v by its estimation from the sample. Either C_v or $\hat{C}_v$ can be used for this purpose ($\hat{C}_v$ being preferable because it is a better estimate). So σ_{C_v} can be estimated as

$$S_{C_v} = \frac{C_v}{\sqrt{2N}} \text{ or } \hat{S}_{C_v} = \frac{\hat{C}_v}{\sqrt{2N}}. \quad (5)$$

Therefore, under the assumption of normality, the statistic

$$t_{C_v} = \frac{C_v - \gamma_v}{S_{C_v}} \quad (6)$$

follows a Student distribution with $v = N - 1$ degrees of freedom. It should be stressed that this test is very sensitive to the normality assumption. Work is still being done to minimize the effect of this assumption.

If Equation 6 is rewritten, confidence intervals can be computed as

$$C_v \pm t_{\alpha, v} S_{C_v} \quad (7)$$

(with $t_{\alpha, v}$ being the critical value of Student's t for the chosen α level and for $v = N - 1$ degrees of freedom). Again, because $\hat{C}_v$ is a better estimation of γ_v than C_v is, it makes sense to use $\hat{C}_v$ rather than C_v .

Example

Table 1 lists the daily commission in dollars of 10 car salespersons. The mean commission is equal to \$200, with a standard deviation of \$40.

This gives a value of the coefficient of variation of

$$C_v = \frac{S}{M} = \frac{40}{200} = 0.200, \quad (8)$$

which corresponds to a population estimate of

$$\hat{C}_v = \left(1 + \frac{1}{4N}\right) C_v = \left(1 + \frac{1}{4 \times 10}\right) \times 0.200 = 0.205. \quad (9)$$

The standard error of the coefficient of variation is estimated as

$$S_{C_v} = \frac{C_v}{\sqrt{2N}} = \frac{0.200}{\sqrt{2 \times 10}} = 0.0447 \quad (10)$$

(the value of $\hat{S}_{C_v}$ is equal to 0.0458).

A t criterion testing the hypothesis that the population value of the coefficient of variation is equal to zero is equal to

$$t_{C_v} = \frac{C_v - \gamma_v}{S_{C_v}} = \frac{0.2000}{0.0447} = 4.47. \quad (11)$$

This value of $t_{C_v} = 4.47$ is larger than the critical value of $t_{\alpha, v} = 2.26$ (which is the critical value of a Student's t distribution for $\alpha = .05$ and $v = .9$ degrees of freedom). Therefore, we can reject the null hypothesis and conclude that γ_v is larger than zero. A 95% corresponding confidence interval gives the values of

$$C_v \pm t_{\alpha, v} S_{C_v} = 0.2000 \pm 2.26 \times 0.0447 = 0.200 \pm 0.1011 \quad (12)$$

and therefore we conclude that there is a probability of .95 that the value of γ_v lies in the interval [0.0989 to 0.3011].

COEFFICIENTS OF ALIENATION AND DETERMINATION

The coefficient of correlation evaluates the similarity of two sets of scores obtained from two variables (or one variable measured twice) within a single sample. It indicates the amount of information common to the two variables. Because this coefficient takes values between -1 and $+1$, it is difficult to interpret or describe its quantitative meaning easily. For example, it is tempting to interpret a positive correlation as a proportion because it is a decimal number between 0 and 1 and looks like a proportion, but that would not be correct. We can square a correlation, however, and that does create a proportion. A squared correlation is called the *coefficient of determination* and gives the proportion of common variance between the two variables. Subtracting the coefficient of determination from 1 gives the proportion of variance *not* shared between two variables. This quantity is called the *coefficient of alienation*.

As an example, imagine a study interested in the conditions that were related to the spread of the coronavirus (COVID-19). In 2020, Denes K. A. Rosario and colleagues conducted a study that looked at the correlation between various weather factors such as solar radiation, temperature, and wind speed measured daily and the number of people infected with COVID-19 daily in six of the cities in the state of Rio de Janeiro in Brazil. The correlation found between wind speed and the infection rate was $-.44$. Theory suggests that wind helps to dilute droplets that spread viruses, so the negative direction of the correlation makes sense. A correlation of this size is often interpreted as moderate to

strong. But what words can one use to describe the size of relationship in a more direct way? Squaring the correlation gives us a coefficient of determination of about .19, so we can say that the two variables (wind speed and number of infections) share 19% of their variance. Other ways of describing this relationship include that there is 19% overlap or the variables share 19% of their information. The coefficient of alienation for this relationship is $1 - .19$ or .81. There was still 81% of the daily number of COVID-19 infections that could be explained by other variables besides wind speed.

The significance of the underlying coefficient of correlation used to compute coefficients of determination or alienation can be tested with an F or a t test. Note that the coefficient of correlation always overestimates the size of the correlation in the population represented by the sample used and needs to be “corrected” in order to provide a better estimation. The corrected value is called *shrunk* or *adjusted*.

The fact that two variables share variance does not mean that one variable causes the other one. *Correlation is not causation*. Use of the term *determination* can be misleading. In our example of a moderate coefficient of determination (.19) between the number of COVID-19 cases in Rio de Janeiro and wind speed, it does not make theoretical sense that the number of cases could cause wind speed, so we would not even consider that possibility. It is more reasonable to assume that wind speed affects the physical spread of the virus, but we still cannot assume a cause-and-effect relationship there. It is possible that some other factor is related to the two variables (e.g., perhaps high wind speeds keep people safely inside, or hot weather affects both wind speed and the survival of the virus in the air).

There are limitations to the somewhat common use of coefficient of determination as an effect size and some have argued that it is better to use the correlation coefficient. Effect sizes are simple quantitative indices used to describe the strength of relationships among variables. Objections to the use of coefficient of determination are sometimes based on a rejection of variance itself as the best way to assess the amount of variability in scores. These critics would prefer that the mean of the absolute deviations be used (instead of squaring them to remove negative values as we do for variance). If this is used as the measure of variability, then the correlation coefficient represents the proportion of variance accounted for pretty well.

COEFFICIENT OF CONCORDANCE

Proposed by Maurice G. Kendall and Bernard Babington Smith, Kendall’s coefficient of concordance (*W*) is a measure of the agreement among several (*m*)

quantitative or semiquantitative variables that are assessing a set of *n* objects of interest. In the social sciences, the variables are often people, called *judges*, assessing different subjects or situations. In community ecology, they may be species whose abundances are used to assess habitat quality at study sites. In taxonomy, they may be characteristics measured over different species, biological populations, or individuals.

There is a close relationship between Milton Friedman’s two-way analysis of variance without replication by ranks and Kendall’s coefficient of concordance. They address hypotheses concerning the same data table, and they use the same χ^2 statistic for testing. They differ only in the formulation of their respective null hypothesis. Consider Table 1, which contains illustrative data. In Friedman’s test, the null hypothesis is that there is no real difference among the *n* objects (sites, rows of Table 1) because they pertain to the same statistical population. Under the null hypothesis, they should have received random ranks along the various variables, so that their sums of ranks should be approximately equal. Kendall’s test focuses on the *m* variables. If the null hypothesis of Friedman’s test is true, this means that the variables have produced rankings of the objects that are independent of one another. This is the null hypothesis of Kendall’s test.

Table 1 Illustrative Example: Ranked Relative Abundances of Four Soil Mite Species (Variables) at 10 Sites (Objects)

	Ranks (column-wise)				Sum of Ranks
	Species 13	Species 14	Species 15	Species 23	Ri
Site 4	5	6	3	5	19.0
Site 9	10	4	8	2	24.0
Site 14	7	8	5	4	24.0
Site 22	8	10	9	2	29.0
Site 31	6	5	7	6	24.0
Site 34	9	7	10	7	33.0
Site 45	3	3	2	8	16.0
Site 53	1.5	2	4	9	16.5
Site 61	1.5	1	1	2	5.5
Site 69	4	9	6	10	29.0

Notes: The ranks are computed columnwise with ties. Right-hand column: sum of the ranks for each site.

Computing Kendall's W

There are two ways of computing Kendall's W statistic (first and second forms of Equations 1 and 2); they lead to the same result. S or S' is computed first from the row-marginal sums of ranks R_i received by the objects:

$$S = \sum_{i=1}^n (R_i - \bar{R})^2 \text{ or } S' = \sum_{i=1}^n R_i^2 = SSR, \quad (1)$$

where S is a sum-of-squares statistic over the row sums of ranks R_i , and $\bar{R}$ is the mean of the R_i values. Following that, Kendall's W statistic can be obtained from either of the following formulas:

$$W = \frac{12S}{m^2(n^3 - n) - mT} \quad \text{or} \quad (2)$$

$$W = \frac{12S' - 3m^2n(n+1)^2}{m^2(n^3 - n) - mT},$$

where n is the number of objects and m is the number of variables. T is a correction factor for tied ranks:

$$T = \sum_{k=1}^g (t_k^3 - t_k), \quad (3)$$

in which t_k is the number of tied ranks in each (k) of g groups of ties. The sum is computed over all groups of ties found in all m variables of the data table. $T = 0$ when there are no tied values.

Kendall's W is an estimate of the variance of the row sums of ranks R_i divided by the maximum possible value the variance can take; this occurs when all variables are in total agreement. Hence $0 \leq W \leq 1$, 1 representing perfect concordance. To derive the formulas for W (Equation 2), one has to know that when all variables are in perfect agreement, the sum of all sums of ranks in the data table (right-hand column of Table 1) is $mn(n+1)/2$ and that the sum of squares of the sums of all ranks is $m^2n(n+1)(2n+1)/6$ (without ties).

There is a close relationship between Charles Spearman's correlation coefficient r_s and Kendall's W statistic: W can be directly calculated from the mean ($\bar{r}_s$) of the pairwise Spearman correlations r_s using the following relationship:

$$W = \frac{(m-1)\bar{r}_s + 1}{m}, \quad (4)$$

where m is the number of variables (judges) among which Spearman correlations are computed. Equation 4 is strictly true for untied observations only; for tied

observations, ties are handled in a bivariate way in each Spearman r_s coefficient whereas in Kendall's W the correction for ties is computed in a single equation (Equation 3) for all variables. For two variables (judges) only, W is simply a linear transformation of r_s : $W = (r_s + 1)/2$. In that case, a permutation test of W for two variables is the exact equivalent of a permutation test of r_s for the same variables.

The relationship described by Equation 4 clearly limits the domain of application of the coefficient of concordance to variables that are all meant to estimate the same general property of the objects: variables are considered concordant only if their Spearman correlations are positive. Two variables that give perfectly opposite ranks to a set of objects have a Spearman correlation of -1 , hence $W = 0$ for these two variables (Equation 4); this is the lower bound of the coefficient of concordance. For two variables only, $r_s = 0$ gives $W = 0.5$. So coefficient W applies well to rankings given by a panel of judges called in to assess overall performance in sports or quality of wines or food in restaurants, to rankings obtained from criteria used in quality tests of appliances or services by consumer organizations, and so forth. It does not apply, however, to variables used in multivariate analysis in which negative as well as positive relationships are informative. Jerrold H. Zar, for example, uses wing length, tail length, and bill length of birds to illustrate the use of the coefficient of concordance. These data are appropriate for W because they are all indirect measures of a common property, the size of the birds.

In ecological applications, one can use the abundances of various species as indicators of the good or bad environmental quality of the study sites. If a group of species is used to produce a global index of the overall quality (good or bad) of the environment at the study sites, only the species that are significantly associated and positively correlated to one another should be included in the index, because different groups of species may be associated to different environmental conditions.

Testing the Significance of W

Friedman's chi-square statistic is obtained from W by the formula

$$\chi^2 = m(n-1)W. \quad (5)$$

This quantity is asymptotically distributed like chi-square with $v = (n-1)$ degrees of freedom; it can be used to test W for significance. According to Kendall and Babington Smith, this approach is satisfactory only for moderately large values of m and n .

Sidney Siegel and N. John Castellan Jr. recommend the use of a table of critical values for W when $n \leq 7$ and $m \leq 20$; otherwise, they recommend testing the chi-square statistic (Equation 5) using the chi-square distribution. Their table of critical values of W for small n and m is derived from a table of critical values of S assembled by Friedman using the z test of Kendall and Babington Smith and reproduced in Kendall's classic monograph, *Rank Correlation Methods*. Using numerical simulations, Pierre Legendre compared results of the classical chi-square test of the chi-square statistic (Equation 5) to the permutation test that Siegel and Castellan also recommend for small samples (small n). The simulation results showed that the classical chi-square test was too conservative for any sample size (n) when the number of variables m was smaller than 20; the test had rejection rates well below the significance level, so it remained valid. The classical chi-square test had a correct level of Type I error (rejecting a null hypothesis that is true) for 20 variables and more. The permutation test had a correct rate of Type I error for all values of m and n . The power of the permutation test was higher than that of the classical chi-square test because of the differences in rates of Type I error between the two tests. The differences in power disappeared asymptotically as the number of variables increased.

An alternative approach is to compute the following F statistic:

$$F = (m - 1)W / (1 - W), \quad (6)$$

which is asymptotically distributed like F with $v_1 = n - 1 - (2/m)$ and $v_2 = v_1(m - 1)$ degrees of freedom. Kendall and Babington Smith described this approach using a Fisher z transformation of the F statistic, $z = 0.5 \log_e(F)$. They recommended it for testing W for moderate values of m and n . Numerical simulations show, however, that this F statistic has correct levels of Type I error for any value of n and m .

In permutation tests of Kendall's W , the objects are the permutable units under the null hypothesis (the objects are sites in Table 1). For the global test of significance, the rank values in all variables are permuted at random, independently from variable to variable because the null hypothesis is the independence of the rankings produced by all variables. The alternative hypothesis is that at least one of the variables is concordant with one, or with some, of the other variables. Actually, for permutation testing, the four statistics SSR (Equation 1), W (Equation 2), χ^2 (Equation 5), and F (Equation 6) are monotonic to one another since n and m , as well as T , are constant within a given permutation test; thus they are equivalent statistics for testing,

producing the same permutational probabilities. The test is one-tailed because it recognizes only positive associations between vectors of ranks. This may be seen if one considers two vectors with exactly opposite rankings: They produce a Spearman statistic of 1, hence a value of zero for W (Equation 4).

Many of the problems subjected to Kendall's concordance analysis involve fewer than 20 variables. The chi-square test should be avoided in these cases. The F test (Equation 6), as well as the permutation test, can safely be used with all values of m and n .

Contributions of Individual Variables to Kendall's Concordance

The overall permutation test of W suggests a way of testing a posteriori the significance of the contributions of individual variables to the overall concordance to determine which of the individual variables are concordant with one or several other variables in the group. There is interest in several fields in identifying discordant variables or judges. This includes all fields that use panels of judges to assess the overall quality of the objects or subjects under study (sports, law, consumer protection, etc.). In other types of studies, scientists are interested in identifying variables that agree in their estimation of a common property of the objects. This is the case in environmental studies in which scientists are interested in identifying groups of concordant species that are indicators of some property of the environment and can be combined into indices of its quality, in particular in situations of pollution or contamination.

The contribution of individual variables to the W statistic can be assessed by a permutation test proposed by Legendre. The null hypothesis is the monotonic independence of the variable subjected to the test, with respect to all the other variables in the group under study. The alternative hypothesis is that this variable is concordant with other variables in the set under study, having similar rankings of values (one-tailed test). The statistic W can be used directly in a posteriori tests. Contrary to the global test, only the variable under test is permuted here. If that variable has values that are monotonically independent of the other variables, permuting its values at random should have little influence on the W statistic. If, on the contrary, it is concordant with one or several other variables, permuting its values at random should break the concordance and induce a noticeable decrease on W .

Two specific partial concordance statistics can also be used in a posteriori tests. The first one is the mean, $\bar{r}_j$, of the pairwise Spearman correlations between variable j under test and all the other variables. The second statistic, W_j , is obtained by applying Equation 4 to $\bar{r}_j$

Table 2 Results of (a) the Overall and (b) the A Posteriori Tests of Concordance Among the Four Species of Table 1; (c) Overall and (d) A Posteriori Tests of Concordance Among Three Species

<i>(a) Overall test of W statistic, four species. H_0: The four species are not concordant with one another.</i>

Notes: $\bar{r}_j$ = mean of the Spearman correlations with the other species; W_j = partial concordance per species; p value = permutational probability (9,999 random permutations); corrected p = Holm-corrected p value. * = Reject H_0 at $\alpha = .05$:

instead of $\bar{r}$, with m the number of variables in the group. These two statistics are shown in Table 2 for the example data; $\bar{r}_j$ and W_j are monotonic to each other because m is constant in a given permutation test. Within a given a posteriori test, W is also monotonic to W_j because only the values related to variable j are permuted when testing variable j . These three statistics are thus equivalent for a posteriori permutation tests, producing the same permutational probabilities. Like $\bar{r}_j$, W_j can take negative values; this is not the case of W .

There are advantages to performing a single a posteriori test for variable j instead of $(m - 1)$ tests of the Spearman correlation coefficients between variable j and all the other variables: The tests of the $(m - 1)$ correlation coefficients would have to be corrected for multiple testing, and they could provide discordant information; a single test of the contribution of variable j to the W statistic has greater power and provides a single, clearer answer. In order to preserve a correct or approximately correct experimentwise error rate, the probabilities of the a posteriori tests computed for

all species in a group should be adjusted for multiple testing.

A posteriori tests are useful for identifying the variables that are not concordant with the others, as in the examples, but they do not tell us whether there are one or several groups of congruent variables among those for which the null hypothesis of independence is rejected. This information can be obtained by computing Spearman correlations among the variables and clustering them into groups of variables that are significantly and positively correlated.

The example data are analyzed in Table 2. The overall permutational test of the W statistic is significant at $\alpha = 5\%$, but marginally (Table 2a). The cause appears when examining the a posteriori tests in Table 2b: Species 23 has a negative mean correlation with the three other species in the group ($\bar{r}_j = .168$). This indicates that Species 23 does not belong in that group. Were we analyzing a large group of variables, we could look at the next partition in an agglomerative clustering dendrogram, or the next K -means partition, and proceed to the overall and a posteriori tests for the members of these new groups. In the present illustrative example, Species 23 clearly differs from the other three species. We can now test Species 13, 14, and 15 as a group. Table 2c shows that this group has a highly significant concordance, and all individual species contribute significantly to the overall concordance of their group (Table 2d).

In Table 2a and 2c, the F test results are concordant with the permutation test results, but due to small m and n , the chi-square test lacks power.

Discussion

The Kendall coefficient of concordance can be used to assess the degree to which a group of variables provides a common ranking for a set of objects. It should be used only to obtain a statement about variables that are all meant to measure the same general property of the objects. It should not be used to analyze sets of variables in which the negative and positive correlations have equal importance for interpretation. When the null hypothesis is rejected, one cannot conclude that all variables are concordant with one another, as shown in Table 2 (a) and (b); only that at least one variable is concordant with one or some of the others.

The partial concordance coefficients and a posteriori tests of significance are essential complements of the overall test of concordance. In several fields, there is interest in identifying discordant variables; this is the case in all fields that use panels of judges to assess the overall quality of the objects under study (e.g., sports, law, consumer protection). In other applications, one is

interested in using the sum of ranks, or the sum of values, provided by several variables or judges, to create an overall indicator of the response of the objects under study. It is advisable to look for one or several groups of variables that rank the objects broadly in the same way, using clustering, and then carry out a posteriori tests on the putative members of each group. Only then can their values or ranks be pooled into an overall index.

COGNITIVE LABORATORY

A cognitive laboratory is a type of qualitative research study where researchers collect observable evidence of participants' unobservable thought processes related to a particular phenomenon. Observable evidence often includes participant verbalizations as they *think aloud during* a phenomenon or provide answers to interview questions retrospectively *after* a phenomenon. Common phenomena explored during labs include the thought processes participants use to solve and mark responses to assessment, survey, or questionnaire items as well as how participants interpret and interact with other types of information such as reading passages, websites, software, or student assessment score reports. This entry introduces two methods of obtaining data during cognitive labs and then briefly summarizes the steps of developing, conducting, and analyzing the results of cognitive lab studies.

The *think aloud* is a common procedure for gathering evidence of participant thought processes. During a think aloud, researchers encourage participants to say what they are thinking as they perform a task. For example, the researcher might prompt a student to “turn on your voice and tell me everything you think about” as they take steps to solve a math problem. The verbalization becomes evidence for how the student is understanding the underlying concepts of the problem and what cognitive processes they use to mark their response.

Think aloud can also be used to explore how individuals interpret other types of information. A think aloud cognitive lab might examine the extent to which parents comprehend or make meaning from different parts of a student score report. For example, a researcher might ask a parent to look at the report and think out loud as they interpret a graph that shows their student’s English language arts score relative to the median scores of the school or state.

Evidence can also be collected with retrospective prompts presented after a question has been answered or the task completed. With retrospective questions, the researcher might ask, “What were you thinking when you answered the question?” or “What did you think about that passage?” In this way, retrospective prompts can be more specific than think aloud prompts, determining which approach to utilize is part of the study’s design and guided by the research questions.

Cognitive lab studies should be designed thoughtfully so that threats to validity are managed in the best ways possible. For example, researchers must specify the research questions, determine how many individuals must be recruited to provide a sample of adequate size and representativeness to answer the questions, plan feasible and reliable data collection procedures, and develop a data analysis plan that yields valid and reliable findings. Since researchers generally administer cognitive labs one-on-one with participants, researchers must balance sample needs against the cost, feasibility, and labor intensiveness of completing the labs with the sample and analyzing the data that the study yields.

Developing reliable procedures is also important to any cognitive lab study design. For example, developing a protocol with a precise script of what questions should be posed to participants and when can help ensure that think aloud and interview prompts are delivered to each participant in a similar way. If using think aloud, the protocol can provide a simple practice experience for participants so that they become comfortable with the concept of speaking their thoughts before the data collection begins. The protocol can also specify how the cognitive lab sessions should be recorded, such as through video or audio recordings, and/or the completion of observation forms.

In addition to recruitment of participants, researchers must determine who will facilitate the labs and make sure that facilitators are adequately trained in the study procedures. Facilitators must understand how to obtain informed consent or assent; follow the protocol; ask open-ended, nonleading questions (if specified by the protocol); operate recording equipment; complete observations forms; and avoid bias during data collection. In addition to receiving training, it can be helpful for staff to practice lab procedures prior to the lab session.

Once the data have been collected, researchers then complete data analysis and reporting. Recordings from lab sessions are frequently transcribed and coded based on the study’s theoretical framework and in response to the research questions and data analysis plan. Researchers synthesize results and develop reports describing the study’s comprehensive findings.

Researchers use results from cognitive labs in a variety of ways. Assessment researchers often use labs to explore whether the cognitive processes that students use to solve and answer items match the constructs that the items were intended to measure. For example, imagine a set of elementary school-level science items that prompt students to use a representation of a food web to answer a question about consumers and producers. Students might use the food web to answer the question, answer the question without interpreting the food web, misinterpret the wording and not understand the question, use background knowledge to answer instead of the food web, or completely guess. Across several items and students, researchers can make inferences about whether students actually use the food web to answer the question as intended.

Findings from cognitive labs can also serve as response process validity evidence. Response process evidence is one of the four sources of validity evidence suggested by the *Standards for Educational and Psychological Testing*. Response process evidence can be used as part of a larger argument that supports valid interpretation of test scores. Additionally, findings from cognitive labs can be used formatively to improve and revise questions or other types of information before they are used with the target population.

COHEN'S *d* STATISTIC

Cohen's *d* statistic is a type of *effect size*. An effect size is a specific numerical nonzero value used to represent the extent to which a null hypothesis is false. As an effect size, Cohen's *d* is typically used to represent the magnitude of differences between two (or more) groups on a given variable, with larger values representing a greater differentiation between the two groups on that variable. When comparing means in a scientific study, the reporting of an effect size such as Cohen's *d* is considered complementary to the reporting of results from a test of statistical significance. Whereas the test of statistical significance is used to suggest whether a null hypothesis is true (no difference exists between Populations A and B for a specific phenomenon) or false (a difference exists between Populations A and B for a specific phenomenon), the calculation of an effect size estimate is used to represent the degree of difference between the two populations in those instances for which the null hypothesis was deemed false. In cases for which the null hypothesis is false (i.e., rejected), the results of a test of statistical significance imply that reliable differences exist between two populations on the phenomenon of interest, but test outcomes do not provide any value regarding the extent of that difference. The calculation of Cohen's *d* and its interpretation provide a way to estimate the actual size of observed differences between two groups, namely, whether the differences are small, medium, or large.

Calculation of Cohen's *d* Statistic

Cohen's *d* statistic is typically used to estimate between-subjects effects for grouped data, consistent with an analysis of variance framework. Often, it is employed within experimental contexts to estimate the differential impact of the experimental manipulation across conditions on the dependent variable of interest. The dependent variable must represent continuous data; other effect size measures (e.g., Pearson family of correlation coefficients, odds ratios) are appropriate for noncontinuous data.

General Formulas

Cohen's *d* statistic represents the standardized mean differences between groups. Similar to other means of standardization such as *z* scoring, the effect size is expressed in standard score units. In general, Cohen's *d* is defined as

$$d = \frac{\mu_1 - \mu_2}{\sigma_e}, \quad (1)$$

where *d* represents the effect size, μ_1 and μ_2 represent the two population means, and σ_e represents the pooled within-group population standard deviation. In practice, these population parameters are typically unknown and estimated by means of sample statistics:

$$\hat{d} = \frac{\bar{Y}_1 - \bar{Y}_2}{S_p}. \quad (2)$$

The population means are replaced with sample means ($\bar{Y}_j$), and the population standard deviation is replaced with S_p , the pooled standard deviation from the sample. The pooled standard deviation is derived by weighing the variance around each sample mean by the respective sample size.

Calculation of the Pooled Standard Deviation

Although computation of the difference in sample means is straightforward in Equation 2, the pooled standard deviation may be calculated in a number of ways. Consistent with the traditional definition of a standard deviation, this statistic may be computed as

$$S_p = \sqrt{\frac{\sum (n_j - 1)s_j^2}{\sum (n_j)}}, \quad (3)$$

where n_j represents the sample sizes for *j* groups and s_j^2 represents the variance (i.e., squared standard deviation) of the *j* samples. Often, however, the pooled sample standard deviation is corrected for bias in its estimation of the corresponding population parameter, σ_e . Equation 4 denotes this correction of bias in the sample statistic (with the resulting effect size often referred to as Hedge's *g*):

$$S_p = \sqrt{\frac{\sum (n_j - 1)s_j^2}{\sum (n_j - 1)}}. \quad (4)$$

When simply computing the pooled standard deviation across two groups, this formula may be reexpressed in a more common format. This formula is suitable for data analyzed with a two-way analysis of variance, such as a treatment–control contrast:

$$S_p = \sqrt{\frac{(n_1 - 1)(s_1^2) + (n_2 - 1)(s_2^2)}{(n_1 - 1) + (n_2 - 1)}} \quad (5)$$

$$= \sqrt{\frac{(n_1 - 1)(s_1^2) + (n_2 - 1)(s_2^2)}{(n_1 + n_2 - 2)}}.$$

The formula may be further reduced to the average of the sample variances when sample sizes are equal in the case of two groups.

$$S_p = \sqrt{\frac{s_j^2}{j}}. \quad (6)$$

or

$$S_p = \sqrt{\frac{s_1^2 + s_2^2}{2}}. \quad (7)$$

Other means of specifying the denominator for Equation 2 are varied. Some formulas use the average standard deviation across groups. This procedure disregards differences in sample size in cases of unequal n when one is weighing sample variances and may or may not correct for sample bias in estimation of the population standard deviation. Further formulas employ the standard deviation of the control or comparison condition (an effect size referred to as Glass's Δ). This method is particularly suited when the introduction of treatment or other experimental manipulation leads to large changes in group variance. Finally, more complex formulas are appropriate when calculating Cohen's d from data involving cluster randomized or nested research designs. The complication partially arises because of the three available variance statistics from which the pooled standard deviation may be computed: the within-cluster variance, the between-cluster variance, or the total variance (combined between- and within-cluster variance). Researchers must select the variance statistic appropriate for the inferences they wish to draw.

Expansion Beyond Two-Group Comparisons: Contrasts and Repeated Measures

Cohen's d always reflects the standardized difference between two means. The means, however, are not restricted to comparisons of two independent groups. Cohen's d may also be calculated in multigroup designs when a specific contrast is of interest. For example, the average effect across two alternative treatments may be compared with a control. The value of the contrast becomes the numerator as specified in Equation 2, and the pooled standard deviation is expanded to include all j groups specified in the contrast (Equation 4).

A similar extension of Equations 2 and 4 may be applied to repeated measures analyses. The difference between two repeated measures is divided by the pooled standard deviation across the j repeated measures. The same formula may also be applied to simple contrasts within repeated measures designs, as well as interaction contrasts in mixed (between- and within-subjects factors) or split-plot designs. Note, however, that the simple application of the pooled standard deviation formula does not take into account the correlation between repeated measures. Researchers disagree as to whether these correlations ought to contribute to effect size computation; one method of determining Cohen's d while accounting for the correlated nature of repeated measures involves computing d from a paired t test.

Additional Means of Calculation

Beyond the formulas presented above, Cohen's d may be derived from other statistics, including the Pearson family of correlation coefficients (r), t tests, and F tests. Derivations from r are particularly useful, allowing for translation among various effect size indices. Derivations from other statistics are often necessary when raw data to compute Cohen's d are unavailable, such as when conducting a meta-analysis of published data. When d is derived as in Equation 3, the following formulas apply:

$$d = \frac{2r}{\sqrt{1-r^2}}, \quad (8)$$

$$d = \frac{t(n_1 + n_2)}{\sqrt{df} \sqrt{n_1 n_2}}, \quad (9)$$

and

$$d = \frac{\sqrt{F}(n_1 + n_2)}{\sqrt{df} \sqrt{n_1 n_2}}. \quad (10)$$

Note that Equation 10 applies only for F tests with 1 degree of freedom (df) in the numerator; further formulas apply when $df > 1$.

When d is derived as in Equation 4, the following formulas ought to be used:

$$d = \frac{2r}{\sqrt{1-r^2}} \sqrt{\frac{df(n_1 + n_2)}{n_1 n_2}}, \quad (11)$$

$$d = t \sqrt{\left(\frac{1}{n_1} + \frac{1}{n_2} \right)}, \quad (12)$$

or

$$d = \sqrt{F \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}. \quad (13)$$

Again, Equation 13 applies only to instances in which the numerator $df = 1$.

These formulas must be corrected for the correlation (r) between dependent variables in repeated measures designs. For example, Equation 12 is corrected as follows:

$$d = t \sqrt{\left(\frac{(1-r)}{n_1} + \frac{(1-r)}{n_2} \right)}. \quad (14)$$

Finally, conversions between effect sizes computed with Equations 3 and 4 may be easily accomplished:

$$d_{eq3} = d_{eq4} \sqrt{\frac{n_1 + n_2}{n_1 + n_2 - 2}} \quad (15)$$

and

$$d_{eq4} = \frac{d_{eq3}}{\sqrt{\frac{n_1 + n_2}{n_1 + n_2 - 2}}}. \quad (16)$$

Variance and Confidence Intervals

The estimated variance of Cohen's d depends on how the statistic was originally computed. When sample bias in the estimation of the population pooled standard deviation remains uncorrected (Equation 3), the variance is computed in the following manner:

$$s_d = \left(\frac{n_1 + n_2}{n_1 n_2} + \frac{d^2}{2(n_1 + n_2 - 2)} \right) \left(\frac{n_1 + n_2}{n_1 + n_2 - 2} \right). \quad (17)$$

A simplified formula is employed when sample bias is corrected as in Equation 4:

$$s_d = \frac{n_1 + n_2}{n_1 n_2} + \frac{d^2}{2(n_1 + n_2 - 2)}. \quad (18)$$

Once calculated, the effect size variance may be used to compute a confidence interval (CI) for the statistic to determine statistical significance:

$$CI = d \pm z(s_d). \quad (19)$$

The z in the formula corresponds to the z -score value on the normal distribution corresponding to the desired probability level (e.g., 1.96 for a 95% CI).

Variances and CIs may also be obtained through bootstrapping methods.

Interpretation

Cohen's d , as a measure of effect size, describes the overlap in the distributions of the compared samples on the dependent variable of interest. If the two distributions overlap completely, one would expect no mean difference between them (i.e., $\bar{Y}_1 - \bar{Y}_2 = 0$). To the extent that the distributions do not overlap, the difference ought to be greater than zero (assuming $\bar{Y}_1 > \bar{Y}_2$).

Cohen's d may be interpreted in terms of both statistical significance and magnitude, with the latter the more common interpretation. Effect sizes are statistically significant when the computed CI does not contain zero. This implies less than perfect overlap between the distributions of the two groups compared. Moreover, the significance testing implies that this difference from zero is reliable, or not due to chance (excepting Type I errors). While significance testing of effect sizes is often undertaken, however, interpretation based solely on statistical significance is not recommended. Statistical significance is reliant not only on the size of the effect but also on the size of the sample. Thus, even large effects may be deemed unreliable when insufficient sample sizes are utilized.

Interpretation of Cohen's d based on the magnitude is more common than interpretation based on statistical significance of the result. The magnitude of Cohen's d indicates the extent of nonoverlap between two distributions, or the disparity of the mean difference from zero. Larger numeric values of Cohen's d indicate larger effects or greater differences between the two means. Values may be positive or negative, although the sign merely indicates whether the first or second mean in the numerator was of greater magnitude (see Equation 2). Typically, researchers choose to subtract the smaller mean from the larger, resulting in a positive effect size. As a standardized measure of effect, the numeric value of Cohen's d is interpreted in standard deviation units. Thus, an effect size of $d = 0.5$ indicates that two group means are separated by one-half standard deviation or that one group shows a one-half standard deviation advantage over the other.

The magnitude of effect sizes is often described nominally as well as numerically. Cohen defined effects as small ($d = 0.2$), medium ($d = 0.5$), or large ($d = 0.8$). These rules of thumb were derived after surveying the behavioral sciences literature, which included studies in various disciplines involving diverse populations, interventions or content under study, and research designs. Cohen, in proposing these benchmarks in a 1988 text, explicitly noted that they are arbitrary and thus ought

not be viewed as absolute. However, as occurred with use of .05 as an absolute criterion for establishing statistical significance, Cohen's benchmarks are oftentimes interpreted as absolutes, and as a result, they have been criticized in recent years as outdated, atheoretical, and inherently nonmeaningful. These criticisms are especially prevalent in applied fields in which medium- to large effects prove difficult to obtain and smaller effects are often of great importance. The small effect of $d = 0.07$, for instance, was sufficient for physicians to begin recommending aspirin as an effective method of preventing heart attacks. Similar small effects are often celebrated in intervention and educational research, in which effect sizes of $d = 0.3$ to $d = 0.4$ are the norm. In these fields, the practical importance of reliable effects is often weighed more heavily than simple magnitude, as may be the case when adoption of a relatively simple educational approach (e.g., discussing vs. not discussing novel vocabulary words when reading storybooks to children) results in effect sizes of $d = 0.25$ (consistent with increases of one fourth of a standard deviation unit on a standardized measure of vocabulary knowledge).

Critics of Cohen's benchmarks assert that such practical or substantive significance is an important consideration beyond the magnitude and statistical significance of effects. Interpretation of effect sizes requires an understanding of the context in which the effects are derived, including the particular manipulation, population, and dependent measure(s) under study. Various alternatives to Cohen's rules of thumb have been proposed. These include comparisons with effects sizes based on (a) normative data concerning the typical growth, change, or differences between groups prior to experimental manipulation; (b) those obtained in similar studies and available in the previous literature; (c) the gain necessary to attain an a priori criterion; and (d) cost-benefit analyses.

Cohen's *d* in Meta-Analyses

Cohen's *d*, as a measure of effect size, is often used in individual studies to report and interpret the magnitude of between-group differences. It is also a common tool used in meta-analyses to aggregate effects across different studies, particularly in meta-analyses involving study of between-group differences, such as treatment studies. A meta-analysis is a statistical synthesis of results from independent research studies (selected for inclusion based on a set of predefined commonalities), and the unit of analysis in the meta-analysis is the data used for the independent hypothesis test, including sample means and standard deviations, extracted from each of the independent studies. The statistical analyses used in the meta-analysis typically involve (a) calculating the Cohen's *d* effect size (standardized mean

difference) on data available within each independent study on the target variable(s) of interest and (b) combining these individual summary values to create pooled estimates by means of any one of a variety of approaches (e.g., Rebecca DerSimonian and Nan Laird's random effects model, which takes into account variations among studies on certain parameters). Therefore, the methods of the meta-analysis may rely on use of Cohen's *d* as a way to extract and combine data from individual studies. In such meta-analyses, the reporting of results involves providing average *d* values (and CIs) as aggregated across studies.

In meta-analyses of treatment outcomes in the social and behavioral sciences, for instance, effect estimates may compare outcomes attributable to a given treatment (Treatment X) as extracted from and pooled across multiple studies in relation to an alternative treatment (Treatment Y) for Outcome Z using Cohen's *d* (e.g., $d = 0.21$, CI = 0.06, 1.03). It is important to note that the meaningfulness of this result, in that Treatment X is, on average, associated with an improvement of about one-fifth of a standard deviation unit for Outcome Z relative to Treatment Y, must be interpreted in reference to many factors to determine the actual significance of this outcome. Researchers must, at the least, consider whether the one-fifth of a standard deviation unit improvement in the outcome attributable to Treatment X has any practical significance.

COHEN'S *f* STATISTIC

Effect size is a measure of the strength of the relationship between variables. Cohen's *f* statistic is one appropriate effect size index to use for a one-way analysis of variance (ANOVA). Cohen's *f* is a measure of a kind of standardized average effect in the population across all the levels of the independent variable.

Cohen's *f* can take on values between zero, when the population means are all equal, and an indefinitely large number as standard deviation of means increases relative to the average standard deviation within each group. Jacob Cohen has suggested that the values of 0.10, 0.25, and 0.40 represent small, medium, and large effect sizes, respectively.

Calculation

Cohen's *f* is calculated as

$$f = \sigma_m / \sigma, \quad (1)$$

where σ_m is the standard deviation (SD) of population means (m_i) represented by the samples and σ is the common within-population SD; $\sigma = MSE^{1/2}$. *MSE* is the mean square of error (within groups) from the overall ANOVA *F* test. It is based on the deviation of the population means from the mean of the combined populations or the mean of the means (*M*).

$$\sigma_m = \left[\sum (m_i - M)^2 / k \right]^{1/2} \quad (2)$$

for equal sample sizes and

$$\sigma_m = \left[\sum n_i (m_i - M)^2 / N \right]^{1/2} \quad (3)$$

for unequal sample sizes.

Examples

Example 1

Table 1 provides descriptive statistics for a study with four groups and equal sample sizes. ANOVA results are shown. The calculations below result in an estimated *f* effect size of .53, which is considered large by Cohen standards. An appropriate interpretation is that about 50% of the variance in the dependent variable (physical health) is explained by the independent variable (presence or absence of mental or physical illnesses at age 16).

$$\begin{aligned} \sigma_m &= \left[\sum (m_i - M)^2 / k \right]^{1/2} = [((71.88 - 62.74)^2 \\ &\quad + (66.08 - 62.74)^2 + (58.44 - 62.74)^2 \\ &\quad + 54.58 - 62.74)^2) / 4]^{1/2} = 6.70 \end{aligned}$$

$$f = \sigma_m / \sigma = 6.70 / 161.29^{1/2} = 6.70 / 12.7 = 0.53$$

Example 2

Table 2 provides descriptive statistics for a study very similar to the one described in Example 1. There are four groups, but the sample sizes are unequal. ANOVA results are shown. The calculations for these samples

Note: Adapted from total sample size of 608 by choosing 80 subjects for each group.

result in an estimated *f* effect size of .27, which is considered medium by Cohen standards. For this study, an appropriate interpretation is that about 25% of the variance in the dependent variable (physical health) is explained by the independent variable (presence or absence of mental or physical illnesses at age 16).

$$\sigma_m = [\sum_i (m_i - M)^2 / N]^{1/2} = [(256 * (72.25 - 67.82)^2 + 89 * (68.16 - 67.82)^2 + 167 * (66.68 - 67.82)^2 + 96 * (57.67 - 67.82)^2) / 608]^{1/2} = 4.99$$

$$f = \sigma_m / \sigma = 4.99 / 340.14^{1/2} = 4.99 / 18.44 = 0.27$$

Cohen's *f* and *d*

Cohen's *f* is an extension of Cohen's *d*, which is the appropriate measure of effect size to use for a *t* test. Cohen's *d* is the difference between two group means divided by the pooled *SD* for the two groups. The relationship between *f* and *d* when one is comparing two means (equal sample sizes) is $d = 2f$. If Cohen's *f* = 0.1, the *SD* of k ($k \geq 2$) population means is one tenth as large as the *SD* of the observations within the populations. For $k = \text{two}$ populations, this effect size indicates a small difference between the two populations: $d = 2f = 2 * 0.10 = 0.2$.

Cohen's *f* in Equation 1 is positively biased because the sample means in Equation 2 or 3 are likely to vary more than do the population means. One can use the

following equation from Scott Maxwell and Harold Delaney to calculate an adjusted Cohen's *f*:

$$f_{adj} = [(k - 1)(F - 1) / N]^{1/2} \quad (4)$$

Applying Equation 4 to the data in Table 1 yields

$$f_{adj} = [(k - 1)(F - 1) / N]^{1/2} = [(4 - 1)(29.72 - 1) / 320]^{1/2} = 0.52.$$

For Table 2,

$$f_{adj} = [(k - 1)(F - 1) / N]^{1/2} = [(4 - 1)(14.84 - 1) / 608]^{1/2} = 0.26.$$

COHEN'S KAPPA

Cohen's Kappa coefficient (κ) is a statistical measure of the degree of agreement or concordance between two independent raters that takes into account the possibility that agreement could occur by chance alone.

Like other measures of interrater agreement, κ is used to assess the reliability of different raters or measurement methods by quantifying their consistency in placing individuals or items in two or more mutually exclusive categories. For instance, in a study of developmental delay, two pediatricians may independently assess a group of toddlers and classify them with respect to their language development into either "delayed for age" or "not delayed." One important aspect of the utility of this classification is the presence of good agreement between the two raters. Agreement between two raters could be simply estimated as the percentage of cases in which both raters agreed. However, a certain degree of agreement is expected by chance alone. In other words, two raters could still agree on some occasions even if they were randomly assigning individuals into either category.

In situations in which there are two raters and the categories used in the classification system have no natural order (e.g., delayed vs. not delayed; present vs. absent), Cohen's κ can be used to quantify the degree of agreement in the assignment of these categories beyond what would be expected by random guessing or chance alone.

Calculation

Specifically, κ can be calculated using the following equation:

$$\kappa = \frac{p_o - p_e}{1 - p_e},$$

where P_o is the proportion of the observed agreement between the two raters, and P_e is the proportion of rater agreement expected by chance alone. A κ of +1 indicates complete agreement, whereas a κ of 0 indicates that there is no agreement between the raters beyond that expected by random guessing or chance alone. A negative κ indicates that the agreement was less than expected by chance, with κ of -1.0 indicating perfect disagreement beyond what would be expected by chance.

Table 1 Data From the Hypothetical Study Described in the Text: Results of Assessments of Developmental Delay Made by Two Pediatricians

Rater 1	Rater 2		Total
	Delayed	Not Delayed	
Delayed	20	3	23
Not delayed	7	70	77
Total	27	73	100

Table 2 Landis and Koch Interpretation of Cohen's

Cohen's Kappa	Degree of Agreement
< 0.20	Poor
0.21–0.40	Fair
0.41–0.60	Moderate
0.61–0.80	Good
0.81–1.00	Very good

Source: Landis & Koch, 1977.

To illustrate the use of the equation, let us assume that the results of the assessments made by the two pediatricians in the above-mentioned example are as shown in Table 1. The two raters agreed on the classification of 90 toddlers (i.e., P_o is 0.90). To calculate the probability of the expected agreement (P_e), we first calculate the probability that both raters would have classified a toddler as delayed if they were merely randomly classifying toddlers to this category. This could be obtained by multiplying the marginal probabilities of the delayed category, that is, $(23 / 100) \times (27 / 100) = 0.062$. Similarly, the probability that both raters would have randomly classified a toddler as not delayed is $(77 / 100) \times (73 / 100) = 0.562$. Therefore, the total agreement expected by chance alone (P_e) is $0.562 + 0.062 = 0.624$. Using the equation, κ is equal to 0.73.

Richard Landis and Gary Koch have proposed the following interpretation for estimates of κ (Table 2). Although arbitrary, this classification is widely used in the medical literature. According to this classification, the agreement between the two pediatricians in the above example is "good."

It should be noted that κ is a summary measure of the agreement between two raters and cannot therefore be used to answer all the possible questions that may arise in a reliability study. For instance, it might be of interest to determine whether disagreement between the two pediatricians in the above example was more likely to occur when diagnosing developmental delay than when diagnosing normal development or vice versa. However, κ cannot be used to address this

question, and alternative measures of agreement are needed for that purpose.

Limitations

It has been shown that the value of κ is sensitive to the prevalence of the trait or condition under investigation (e.g., developmental delay in the above example) in the study population. Although two raters may have the same degree of agreement, estimates of κ might be different for a population in which the trait under study is very common compared with another population in which the trait is less prevalent.

Cohen's κ does not take into account the seriousness of the disagreement. For instance, if a trait is rated on a scale that ranges from 1 to 5, all disagreements are treated equally, whether the raters disagreed by 1 point (e.g., 4 vs. 5) or by 4 points on the scale (e.g., 1 vs. 5). Cohen introduced *weighted* κ for use with such ordered scales. By assigning weights to each disagreement pair, it is possible to incorporate a measure of the seriousness of the disagreement, for instance by assigning larger weights to more severe disagreement.

Both κ and weighted κ are limited to cases in which there are only two raters. Alternative measures of agreements (e.g., Fleiss' κ) can be used in situations in which there are more than two raters and in which study subjects are not necessarily always rated by the same pair of raters.

COHORT DESIGN

In epidemiology, a cohort design or cohort study is a nonexperimental study design that involves comparing the occurrence of a disease or condition in two or more

groups (or *cohorts*) of people that differ on a certain characteristic, risk factor, or exposure. The disease, state, or condition under study is often referred to as the *outcome*, whereas the characteristic, risk factor, or exposure is often referred to as the *exposure*. A cohort study is one of two principal types of nonexperimental study designs used to study the causes of disease. The other is the case-control design, in which cases of the disease under study are compared with respect to their past exposure with a similar group of individuals who do not have the disease.

Cohort (from the Latin *cohors*, originally a unit of a Roman legion) is the term used in epidemiology to refer to a group of individuals who share a common characteristic; for example, they may all belong to the same ethnic or age group or be exposed to the same risk factor (e.g., radiation or soil pollution).

The cohort study is a relatively recent innovation. The first cohort studies were used to confirm the link between smoking and lung cancer that had been observed initially in earlier case-control studies. Cohort studies also formed the basis for much of the early progress in understanding occupational diseases. Cohort studies based on data derived from company records and vital records led to the identification of many environmental and occupational risk factors. Several major cohort studies with follow-up that spanned decades have made significant contributions to our understanding of the causes of several common chronic diseases. Examples include the Framingham Heart Study, the Tecumseh Community Health Study, the British Doctors Study, and the Nurses' Health Study.

In a classic cohort study, individuals who are initially free of the disease being researched are enrolled into the study, and individuals are each categorized into one of two groups according to whether they have been exposed to the suspected risk factor. One group, called the *exposed group*, includes individuals known to have the characteristic or risk factor under study. For instance, in a cohort study of the effect of smoking on lung cancer, the exposed group may consist of known smokers. The second group, the *unexposed group*, will comprise a comparable group of individuals who are also free of the disease initially but are nonsmokers. Both groups are then followed up for a predetermined period of time or until the occurrence of disease or death. Cases of the disease (lung cancer in this instance) occurring among both groups are identified in the same way for both groups. The number of people diagnosed with the disease in the exposed group is compared with that among the unexposed group to estimate the relative risk of disease due to the exposure or risk factor. This type of design is sometimes called a *prospective cohort study*.

In a *retrospective (historical) cohort study*, the researchers use existing records or electronic databases to identify individuals who were exposed at a certain point in the past and then “follow” them up to the present. For instance, to study the effect of exposure to radiation on cancer occurrence among workers in a uranium mine, the researcher may use employee radiation exposure records to categorize workers into those who were exposed to radiation and those who were not at a certain date in the past (e.g., 10 years ago). The medical records of each employee are then searched to identify those employees who were diagnosed with cancer from that date onward. Like prospective cohort designs, the frequency of occurrence of the disease in the exposed group is compared with that within the unexposed group in order to estimate the relative risk of disease due to radiation exposure. When accurate and comprehensive records are available, this approach could save both time and money. But unlike the classic cohort design, in which information is collected prospectively, the researcher employing a retrospective cohort design has little control over the quality and availability of information.

Cohort studies could also be classified as closed or open cohort studies. In a *closed cohort study*, cohort membership is decided at the onset of the study, and no additional participants are allowed to join the cohort once the study starts. For example, in the landmark British Doctors Study, participants were male doctors who were registered for medical practice in the United Kingdom in 1951. This cohort was followed up with periodic surveys until 2001. This study provided strong evidence for the link between smoking and several chronic diseases, including lung cancer.

In an *open (dynamic) cohort study*, the cohort membership may change over time as additional participants are permitted to join the cohort, and they are followed up in a fashion similar to that of the original participants. For instance, in a prospective study of the effects of radiation on cancer occurrence among uranium miners, newly recruited miners are enrolled in the study cohort and are followed up in the same way as those miners who were enrolled at the inception of the cohort study.

Regardless of their type, cohort studies are distinguished from other epidemiological study designs by having all the following features:

- The study group or groups are observed over time for the occurrence of the study outcome.
- The study group or groups are defined on the basis of whether they have the exposure at the start or during the observation period before the occurrence of the

outcome. Therefore, in a cohort study, it is always clear that the exposure has occurred before the outcome.

- Cohort studies are observational or nonexperimental studies. Unlike clinical trials, the cohort study design does not usually involve manipulating the exposure under study in any way that changes the exposure status of the participants.

Advantages and Disadvantages

Cohort studies are used instead of experimental study designs, such as clinical trials, when experiments are not feasible for practical or ethical reasons, such as when investigating the effects of a potential cause of disease.

In contrast to case-control studies, the design of cohort studies is intuitive, and their results are easier to understand by nonspecialists. Furthermore, the temporal sequence of events in a cohort study is clear because it is always known that the exposure has occurred before the disease. In case-control and cross-sectional studies, it is often unclear whether the suspected exposure has led to the disease or the other way around.

In prospective cohort studies, the investigator has more control over what information is to be collected and at what intervals. As a result, the prospective cohort design is well suited for studying chronic diseases because it permits fuller understanding of the disease's natural history.

In addition, cohort studies are typically better than case-control studies in studying rare exposures. For instance, case-control designs are not practical in studying occupational exposures that are rare in the general population, as when exposure is limited to a small cohort of workers in a particular industry. Another advantage of cohort studies is that multiple diseases and conditions related to the same exposure could be easily examined in one study.

On the other hand, cohort studies tend to be more expensive and take longer to complete than other nonexperimental designs. Generally, case-control and retrospective cohort studies are more efficient and less expensive than the prospective cohort studies. The prospective cohort design is not suited for the study of rare diseases, because prospective cohort studies require following up a large number of individuals for a long time. Maintaining participation of study subjects over time is a challenge, and selective dropout from the study (or loss to follow-up) may result in biased results. Because of lack of randomization, cohort studies are more potentially subject to bias and confounding than experimental studies are.

Design and Implementation

The specifics of cohort study design and implementation depend on the aim of the study and the nature of the risk factors and diseases under study. However, most prospective cohort studies begin by assembling one or more groups of individuals. Often members of each group share a well-defined characteristic or exposure. For instance, a cohort study of the health effects of uranium exposure may begin by recruiting all uranium miners employed by the same company, whereas a cohort study of the health effects of exposure to soil pollutants from a landfill may include all people living within a certain distance from the landfill. Several major cohort studies have recruited all people born in the same year in a city or province (birth cohorts). Others have included all members of a professional group (e.g., physicians or nurses), regardless of where they lived or worked. Yet others were based on a random sample of the population. Cohort studies of the natural history of disease may include all people diagnosed with a precursor or an early form of the disease and then followed up as their disease progressed.

The next step is to gather information on the exposure under investigation. Cohort studies can be used to examine exposure to external agents, such as radiation, secondhand smoke, an infectious agent, or a toxin. But they can also be used to study the health effects of internal states (e.g., possession of a certain gene), habits (e.g., smoking or physical inactivity), or other characteristics (e.g., level of income or educational status). The choice of the appropriate exposure measurement method is an important design decision and depends on many factors, including the accuracy and reliability of the available measurement methods, the feasibility of using these methods to measure the exposure for all study participants, and the cost.

In most prospective cohort studies, baseline information is collected on all participants as they join the cohort, typically using self-administered questionnaires or phone or in-person interviews. The nature of the collected information depends on the aim of the study but often includes detailed information on the exposure(s) under investigation. In addition, information on demographic and socioeconomic factors (e.g., age, gender, and occupation) is often collected. As in all observational studies, information on potential confounders, factors associated with both the exposure and outcome under study that could confuse the interpretation of the results, is also collected. Depending on the type of the exposure under study, the study design may also include medical examinations of study participants, which may include clinical assessment (e.g., measuring blood pressure), laboratory testing (e.g., measuring

blood sugar levels or testing for evidence for an infection with a certain infectious agent), or radiological examinations (e.g., chest x-rays). In some studies, biological specimens (e.g., blood or serum specimens) are collected and stored for future testing.

Follow-up procedures and intervals are also important design considerations. The primary aim of follow-up is to determine whether participants developed the outcome under study, although most cohort studies also collect additional information on exposure and confounders to determine changes in exposure status (e.g., a smoker who quits smoking) and other relevant outcomes (e.g., development of other diseases or death). As with exposures, the method of collecting information on outcomes depends on the type of outcome and the degree of desired diagnostic accuracy. Often, mailed questionnaires and phone interviews are used to track participants and determine whether they developed the disease under study. For certain types of outcome (e.g., death or development of cancer), existing vital records (e.g., the National Death Index in the United States) or cancer registration databases could be used to identify study participants who died or developed cancer. Sometimes, in-person interviews and clinic visits are required to accurately determine whether a participant has developed the outcome, as in the case of studies of the incidence of often asymptomatic diseases such as hypertension or HIV infection.

In certain designs, called *repeated measurements designs*, the above measurements are performed more than once for each participant. Examples include *pre-post exposure studies*, in which an assessment such as blood pressure measurement is made before and after an intervention such as the administration of an antihypertensive medication. Pre-post designs are more commonly used in experimental studies or clinical trials, but there are occasions where this design can be used in observational cohort studies. For instance, results of hearing tests performed during routine preemployment medical examinations can be compared with results from hearing tests performed after a certain period of employment to assess the effect of working in a noisy workplace on hearing acuity.

In *longitudinal repeated measurements designs*, typically two or more exposure (and outcome) measurements are performed over time. These studies tend to be observational and could therefore be carried out prospectively or less commonly retrospectively using precollected data. These studies are ideal for the study of complex phenomena such as the natural history of chronic diseases, including cancer. The repeated measurements allow the investigator to relate changes in time-dependent exposures to the dynamic status of the disease or condition under study. This is especially

valuable if exposures are transient and may not be measurable by the time the disease is detected. For instance, repeated measurements are often used in longitudinal studies to examine the natural history of cervical cancer as it relates to infections with the human papilloma virus. In such studies, participants are typically followed up for years with prescheduled clinic visits at certain intervals (e.g., every 6 months). At each visit, participants are examined for evidence of infection with human papilloma virus or development of cervical cancer. Because of the frequent testing for these conditions, it is possible to acquire a deeper understanding of the complex sequence of events that terminates with the development of cancer.

One important goal in all cohort studies is to minimize voluntary loss to follow-up due to participants' dropping out of the study or due to researchers' failure to locate and contact all participants. The longer the study takes to complete, the more likely that a significant proportion of the study participants will be lost to follow-up because of voluntary or involuntary reasons (e.g., death, migration, or development of other diseases). Regardless of the reasons, loss to follow-up is costly because it reduces the study's sample size and therefore its statistical power. More important, loss to follow-up could bias the study results if the remaining cohort members differ from those who were lost to follow-up with respect to the exposure under study. For instance, in a study of the effects of smoking on dementia, smoking may misleadingly appear to reduce the risk of dementia because smokers are more likely than nonsmokers to die at younger age, before dementia could be diagnosed.

Analysis of Data

Compared with other observational epidemiologic designs, cohort studies provide data permitting the calculations of several types of disease occurrence measures, including disease prevalence, incidence, and cumulative incidence. Typically, disease incidence rates are calculated separately for each of the exposed and the unexposed study groups. The ratio between these rates, the *rate ratio*, is then used to estimate the degree of increased risk of the disease due to the exposure.

In practice, more sophisticated statistical methods are needed to account for the lack of randomization. These methods include direct or indirect standardization, commonly used to account for differences in the age or gender composition of the exposed and unexposed groups. *Poisson regression* could be used to account for differences in one or more confounders. Alternatively, life table and other survival analysis methods, including *Cox proportional hazard models*, could be used to analyze data from cohort studies.

Special Types

Nested Case–Control Studies

In a nested case–control study, cases and controls are sampled from a preexisting and usually well-defined cohort. Typically, all subjects who develop the outcome under study during follow-up are included as cases. The investigator then randomly samples a subset of noncases (subjects who did not develop the outcome at the time of diagnosis of cases) as controls. Nested case–control studies are more efficient than cohort studies because exposures are measured only for cases and a subset of noncases rather than for all members of the cohort.

For example, to determine whether a certain hormone plays a role in the development of prostate cancer, one could assemble a cohort of men, measure the level of that hormone in the blood of all members of the cohort, and then follow up with them until development of prostate cancer. Alternatively, a nested case–control design could be employed if one has access to a suitable cohort. In this scenario, the investigator would identify all men in the original cohort who developed prostate cancer during follow-up (the cases). For each case, one or more controls would then be selected from among the men who were still alive and free of prostate cancer at the time of the case's diagnosis. Hormone levels would be then measured for only the identified cases and controls rather than for all members of the cohort.

Nested case–control designs have most of the strengths of prospective cohort studies, including the ability to demonstrate that the exposure occurred before the disease. However, the main advantage of nested case–control designs is economic efficiency. Once the original cohort is established, nested case–control designs require far less financial resources and are quicker in producing results than establishing a new cohort. This is especially the case when outcomes are rare or when the measurement of the exposure is costly in time and resources.

Case–Cohort Studies

Similar to the nested case–control study, in a case–cohort study, cases and controls are sampled from a preexisting and usually well-defined cohort. However, the selection of controls is not dependent on the time spent by the noncases in the cohort. Rather the adjustment for confounding effects of time is performed during analysis. Case–cohort studies are more efficient and economical than full cohort studies, for the same reasons that nested case–control studies are economical. In

addition, the same set of controls can be used to study multiple outcomes or diseases.

COLLINEARITY

Collinearity is a situation in which the predictor, or exogenous, variables in a linear regression model are linearly related among themselves or with the intercept term, and this relation may lead to adverse effects on the estimated model parameters, particularly the regression coefficients and their associated standard errors. In practice, researchers often treat correlation between predictor variables as collinearity, but strictly speaking they are not the same; strong correlation implies collinearity, but the opposite is not necessarily true. When there is strong collinearity in a linear regression model, the model estimation procedure is not able to uniquely identify the regression coefficients for highly correlated variables or terms and therefore cannot separate the covariate effects. This lack of identifiability affects the interpretability of the regression model coefficients, which can cause misleading conclusions about the relationships between variables under study in the model.

Consequences of Collinearity

There are several negative effects of strong collinearity on estimated regression model parameters that can

interfere with inference on the relationships of predictor variables with the response variable in a linear regression model. First, the interpretation of regression coefficients as marginal effects is invalid with strong collinearity, as it is not possible to hold highly correlated variables constant while increasing another correlated variable one unit. In addition, collinearity can make regression coefficients unstable and very sensitive to change. This is typically manifested in a large change in magnitude or even a reversal in sign in one regression coefficient after another predictor variable is added to the model or specific observations are excluded from the model. It is especially important for inference that a possible consequence of collinearity is a sign for a regression coefficient that is counterintuitive or counter to previous research. The instability of estimates is also realized in very large or inflated standard errors of the regression coefficients. The fact that these inflated standard errors are used in significance tests of the regression coefficients leads to conclusions of insignificance of regression coefficients, even, at times, in the case of important predictor variables. In contrast to inference on the regression coefficients, collinearity does not impact the overall fit of the model to the observed response variable data.

Diagnosing Collinearity

There are several commonly used exploratory tools to diagnose potential collinearity in a regression model. The numerical instabilities in analysis caused by collinearity among regression model variables lead to correlation between the estimated regression coefficients, so some techniques assess the level of correlation in both the predictor variables and the coefficients. Coefficients of correlation between pairs of predictor variables are statistical measures of the strength of association between variables. *Scatterplots* of the values of pairs of predictor variables provide a visual description of the correlation among variables, and these tools are used frequently. There are, however, more direct ways to assess collinearity in a regression model by inspecting the model output itself. One way to do so is through coefficients of correlation of pairs of estimated regression coefficients. These statistical summary measures allow one to assess the level of correlation among different pairs of covariate effects as well as the correlation between covariate effects and the intercept. Another way to diagnose collinearity is through *variance inflation factors*, which measure the amount of increase in the estimated variances of regression coefficients compared with when predictor variables are uncorrelated. Drawbacks of the variance inflation factor as a collinearity diagnostic tool are that

it does not illuminate the nature of the collinearity, which is problematic if the collinearity is between more than two variables, and it does not consider collinearity with the intercept. A diagnostic tool that accounts for these issues consists of variance-decomposition proportions of the regression coefficient variance–covariance matrix and the condition index of the matrix of the predictor variables and constant term. Some less formal diagnostics of collinearity that are commonly used are a counterintuitive sign in a regression coefficient, a relatively large change in value for a regression coefficient after another predictor variable is added to the model, and a relatively large standard error for a regression coefficient. Given that statistical inference on regression coefficients is typically a primary concern in regression analysis, it is important for one to apply diagnostic tools in a regression analysis before interpreting the regression coefficients, as the effects of collinearity could go unnoticed without a proper diagnostic analysis.

Remedial Methods for Collinearity

There are several methods in statistics that attempt to overcome collinearity in standard linear regression models. These methods include *principal components regression*, *ridge regression*, and a technique called the *lasso*. Principal components regression is a variable subset selection method that uses combinations of the exogenous variables in the model, and ridge regression and the lasso are penalization methods that add a constraint on the magnitude of the regression coefficients. Ridge regression was designed precisely to reduce collinearity effects by penalizing the size of regression coefficients. The lasso also shrinks regression coefficients, but it shrinks the least significant variable coefficients toward zero to remove some terms from the model. Ridge regression and the lasso are considered superior to principal components regression to deal with collinearity in regression models because they more purposely reduce inflated variance in regression coefficients due to collinearity while retaining interpretability of individual covariate effects.

Future Research

While linear regression models offer the potential for explaining the nature of relationships between variables in a study, collinearity in the exogenous variables and intercept can generate curious results in the estimated regression coefficients that may lead to incorrect substantive conclusions about the relationships of interest. More research is needed regarding the level of

collinearity that is acceptable in a regression model before statistical inference is unduly influenced.

COLUMN GRAPH

A column graph summarizes categorical data by presenting parallel vertical bars with a height (and hence area) proportionate to specific quantities of data for each category. This type of graph can be useful in comparing two or more distributions of nominal- or ordinal-level data.

Developing Column Graphs

A column graph can and should provide an easy-to-interpret visual representation of a frequency or percentage distribution of a single (or multiple) variable(s). Column graphs present a series of vertical equal-width rectangles, each with a height proportional to the frequency (or percentage) of a specific category of observations. Categories are labeled on the x-axis (the horizontal axis), and frequencies are labeled on the y-axis (the vertical axis). For example, a column graph that displays the partisan distribution of a single session of a state legislature would consist of at least two rectangles, one representing the number of Democratic seats, one representing the number of Republican seats, and perhaps one representing the number of independent seats. The x-axis would consist of the “Democratic” and “Republican” labels while the y-axis would consist of labels representing intervals for the number of seats in the state legislature.

When developing a column graph, it is vital that the researcher present a set of categories that is both exhaustive and mutually exclusive. In other words, each potential value must belong to one and only one category. Developing such a category schema is relatively easy when the researcher is faced with discrete data, in which the number observations for a particular value can be counted (i.e. nominal- and ordinal-level data). For nominal data, the categories are unordered, with interchangeable values (e.g., gender, ethnicity, religion). For ordinal data, the categories exhibit some type of relation to each other, although the relation does not exhibit specificity beyond ranking the values (e.g., greater than vs. less than, agree strongly vs. agree vs. disagree vs. disagree strongly). Because nominal and ordinal data are readily countable, once the data are obtained, the counts can then be readily transformed into a column graph.

With continuous data (i.e., interval- and ratio-level data), an additional step is required. For interval data, the distance between observations is fixed (e.g., Carolyn makes \$5,000 more per year than John does). For ratio-level data, the data can be measured as in relation to a fixed point (e.g., a family's income falls a certain percentage above or below the poverty line). For

continuous data, the number of potential values can be infinite or, at the very least, extraordinarily high, thus producing a cluttered chart. Therefore, it is best to reduce interval- or ratio-level data to ordinal-level data by collapsing the range of potential values into a few select categories. For example, a survey that asks respondents for their age could produce dozens of potential answers, and therefore it is best to condense the variable into a select few categories (e.g., 18–25, 26–35, 36–45, 46–64, 65 and older) before making a column graph that summarizes the distribution.

Multiple Distribution Column Graphs

Column graphs can also be used to compare multiple distributions of data. Rather than presenting a single set of vertical rectangles that represents a single distribution of data, column graphs present multiple sets of rectangles, one for each distribution. For ease of interpretation, each set of rectangles should be grouped together and separate from the other distributions. This type of graph can be particularly useful in comparing counts of observations across different categories of interest. For example, a researcher conducting a survey might present the aggregate distribution of self-reported

Figure 1 1990–2009 Illinois House Partisan Distribution (Column Graph)

Source: *Almanac of Illinois Politics*. (2009). Springfield: Illinois Issues.

partisanship, but the researcher can also demonstrate the gender gap by displaying separate partisan distributions for male and female respondents. By putting each distribution into a single graph, the researcher can visually present the gender gap in a readily understandable format.

Column graphs might also be used to explore chronological trends in distributions. One such example is in Figure 1, which displays the partisan makeup of the Illinois state House from the 1990 through the 2008 elections. The black bars represent the number of Republican seats won in the previous election (presented on the x-axis) and the gray bars represent the number of Democratic seats. By showing groupings of the two partisan bars side by side, the graph provides for an easy interpretation of which party had control of the legislative chamber after a given election. Furthermore, readers can look across each set of bars to determine the extent to which the partisan makeup of the Illinois House has changed over time.

Stacked Column

One special form of the column graph is the stacked column, which presents data from a particular

distribution in a single column. A regular stacked column places the observation counts directly on top of one another, while a 100% stacked column does the same while modifying each observation count into a percentage of the overall distribution of observations. The former type of graph might be useful when the researcher wishes to present a specific category of interest (which could be at the bottom of the stack) and the total number of observations. The latter might be of interest when the researcher wants a visual representation of how much of the total distribution is represented by each value and the extent to which that distribution is affected by other variables of interest (such as time). Either version of the stacked column approach can be useful in comparing multiple distributions, such as with Figure 2, which presents a 100% stacked column representation of chronological trends in Illinois House partisan makeup.

Column Graphs and Other Figures

When one is determining whether to use a column graph or some other type of visual representation of relevant data, it is important to consider the main features of other types of figures, particularly the level of

Figure 2 1990–2009 Illinois House Partisan Distribution (100% Stacked Column Graph)

Source: *Almanac of Illinois Politics*. (2009). Springfield: Illinois Issues.

measurement and the number of distributions of interest.

Bar Graph

A column graph is a specific type of bar graph (or chart). Whereas the bar graph can present summaries of categorical data in either vertical or horizontal rectangles, a column graph presents only vertical rectangles. The decision to present horizontal or vertical representations of the data is purely aesthetic, and so the researcher might want to consider which approach would be the most visually appealing, given the type of analysis presented by the data.

Pie Chart

A pie chart presents the percentage of each category of a distribution as a segment of a circle. This type of graph allows for only a single distribution at a time; multiple distributions require multiple pie charts. As with column and bar graphs, pie charts represent observation counts (or percentages) and thus are used for discrete data, or at the very least

continuous data collapsed into a select few discrete categories.

Line Graph

A line graph displays relationships between two changing variables by drawing a line that connects actual or projected values of a dependent variable (y-axis) based on the value of an independent variable (x-axis). Because line graphs display trends between plots of observations across an independent variable, neither the dependent nor the independent variable can contain nominal data. Furthermore, ordinal data do not lend themselves to line graphs either, because the data are ordered only within the framework of the variables. As with column graphs and bar graphs, line graphs can track multiple distributions of data based on categories of a nominal or ordinal variable. Figure 3 provides such an example, with yet another method of graphically displaying the Illinois House partisan makeup. The election year serves as the independent variable, and the number of Illinois House seats for a particular party as the dependent variable. The solid gray and dotted black lines present the respective

Democratic and Republican legislative seat counts, allowing for easy interpretation of the partisan distribution trends.

Histogram

A histogram is a special type of column graph that allows for a visual representation of a single frequency distribution of interval or ratio data without collapsing the data to a few select categories. Visually, a histogram looks similar to a column graph, but without any spaces between the rectangles. On the x-axis, a histogram displays intervals rather than discrete categories. Unlike a bar graph or a column graph, a histogram only displays distributions and cannot be used to compare multiple distributions. The histogram in Figure 4 displays the distribution of a political knowledge variable obtained via a 2004 survey of University of Illinois undergraduate students. The survey included a series of 19 questions about U.S. government and politics.

COMPARISON-FOCUSED SAMPLING

Comparison-focused sampling (CFS) is a sampling method used to compare and contrast two or more different cases or occasions for an in-depth analysis. Recently, sampling techniques have been raised as a matter of importance in both qualitative and quantitative methods. A number of scholars, statisticians, and even practitioners sometimes struggle with comparing several outputs of sampling. In particular, the differences between empirical and practical samples have been confused, which might then cause the resulting argument and/or the analysis itself to be misleading. Hence, Michael Quinn Patton in 2015 presented CFS, a useful method to minimize—or even eliminate—such confusions. In his 2015 book *Qualitative Research & Evaluation Methods: Integrating Theory and Practice*, Patton states, “the logic and power of purposeful sampling lies in selecting information rich cases for in-depth study” (p. 264). This novel sampling technique facilitates more efficient comparisons between two cases, resulting in a deeper analysis.

The Starting Theoretical Framework

In particular, CFS investigates significant similarities and/or divergences in depth in order to effectively detect the main insightful factors supporting the interpretation of those significant differences. For an outlier sampling analysis in a program’s evaluation, for instance, CFS works by comparing successes (high outcomes) with failures (low outcomes and dropouts).

Likewise, the study of top achievers’ behaviors, excellent organizations and modes in actions, and/or outstanding communities compared to great mistakes and disasters manifesting significant ineffectiveness in similar conditions (e.g., frictions, distortions, disturbances, misalignments, misunderstandings) could be another example of CFS. In general, for CFS, it is preferable to choose a small sample size of groups in order to better conduct an in-depth case analysis.

Comparison-Focused Sampling Versus Other Types of Samplings

Although CFS is a novel technique, there are many other sampling strategies existing in the literature, such as the following:

- *Single significant case.* The single significant case represents one sample in-depth case (where n is equal to 1) that contributes to rich and deep understanding

of the main subject and provides advanced distinctive insights of its own standout features. (i.e., exemplar of a special thing of interest).

- *Group characteristics sampling.* The group characteristics sampling strategy provides case selection in order to establish a specific enriched information group that might disclose and clarify principal or key patterns (i.e., illuminating patterns in a group).
- *Theory-focused and concept sampling.* Theory-focused and concept sampling includes cases that are exemplars of the main argument or concept pertaining to the focus question in order to enlighten the theoretical hypothesis of interest (i.e., deductive theoretical sampling).
- *Instrumental-use multiple case sampling.* This sampling techniques captures more than one case of a circumstance with the aim to generate standard outputs that might be used to change some practice, program, or policy (i.e., utilization-focused sampling).
- *Sequential and emergence-driven sampling.* With sequential and emergence-driven sampling, one case after another are investigated in sequence to build the sample fieldwork. Then, new findings can emerge during this research after analyzing further leads (i.e., snowball sampling).
- *Analytically focused sampling.* This sampling technique involves selecting cases in order to facilitate a deeper qualitative analysis and interpretation of patterns among the defined cases. It also establishes a form of emergent not expected sampling during the analysis (i.e., emergent sampling).
- *Mixed, stratified, and nested sampling.* With mixed, stratified, and nested sampling, multiple cases are investigated through focused in-depth analysis, creating relative bounds for emerging relevance and credibility (i.e., mixed methods).

CFS includes some features of all the aforementioned sampling techniques and as such can address well-known difficulties in analysis, such as predicting and estimating future trends.

The Systems Implementation of Comparison-Focused Sampling

Case selection is the most important step in CFS. With regard to sufficient sample size, the research design mostly depends on the aim of the study and the specific estimated contribution of each study to existing theory, the available data sets and materials, and the sampling strategy already implemented.

Methodologically, when the use of new observations to advance a hypothesis, and findings in various studies replicated, a multicase approach seems appropriate. This method can be crucial in some situations such as when increased complexity and surrounding uncertainty influences the observers' ability to interpret what really is going on. Such a situation may result in relevant dynamics and interconnections, or lots of information, being hidden, and as a consequence, the final rendering may be confusing.

When complexity in CFS takes place, a holistic approach—such as the System Thinking, and Viable Systems Approach as presented by Sergio Barile and colleagues—can foster a conscious analysis of systems dynamics. This approach proposes a layered way of investigating several factors in exchanges and focusing on the specific aim or will of all involved actors interacting with each other. This, then, provides an original contribution to the analysis as a whole, thus, CFS can be fostered and supported by the use of a systems lens (namely S-CFS).

Benefits of Using S-CFS

In literature, a specific research methodology in the manner of a *super diversity* concept does not exist; however, it can be stated that S-CFS can support a good analysis by taking into account some system aspects or dimensions of complexity, such as variety, variability, and indeterminacy. In the field of comparing and contrasting analysis aimed to explore significant similarities and/or differences, CFS, implemented as S-CFS, can be a reliable strategy to reach significance among samples in any research.

Fundamentally, scholars need to ensure an inclusive sampling strategy; in this sense, S-CFS provides various contextualized information (input) as they are detectable in a stated moment; interpretational variables and schemes (throughput) to properly filter, cluster, and elaborate data; and a viable system lens to find out a consistent and solid meaning or explanation of such an observed phenomenon (output).

COMPLETELY RANDOMIZED DESIGN

A completely randomized design (CRD) is the simplest design for comparative experiments, as it uses only two basic principles of experimental designs: *randomization* and *replication*. Its power is best understood in the context of agricultural experiments (for which it was initially developed), and it will be discussed from that perspective, but true experimental designs, where feasible, are useful in the social sciences and in medical experiments.

In CRDs, the treatments are allocated to the experimental units or plots in a completely random manner. CRD may be used for single- or multifactor experiments. This entry discusses the application, advantages, and disadvantages of CRD studies and the processes of conducting and analyzing them.

Application

CRD is mostly useful in laboratory and green house experiments in agricultural, biological, animal, environmental, and food sciences, where experimental material is reasonably homogeneous. It is more difficult when the experimental units are people.

Advantages and Disadvantages

This design has several advantages. It is very flexible as any number of treatments may be used, with equal or unequal replications. The design has a comparatively simple statistical analysis and retains this simplicity even if some observations are missing or lost accidentally. The design provides maximum degrees of freedom for the estimation of error variance, which increases the precision of an experiment.

However, the design is not suitable if a large number of treatments are used and the experimental material is not reasonably homogeneous. Therefore, it is seldom used in agricultural field experiments in which soil

heterogeneity may be present because of soil fertility gradient or in animal sciences when the animals (experimental units) vary in such things as age, breed, or initial body weight, or with people.

Layout of the Design

The plan of allocation of the treatments to the experimental material is called the layout of the design.

Let the *i*th ($i = 1, 2, \dots, v$) treatments be replicated r_i times. Therefore, $N = \sum r_i$ is the total number of required experimental units.

The treatments are allocated to the experimental units or plots in a completely random manner. Each treatment has equal probability of allocation to an experimental unit.

Given below is layout plan of CRD with four treatments, denoted by integers, each replicated 3 times and allocated to 12 experimental units.

3	2	4	4
3	1	4	1
3	1	2	2

Randomization

Some common methods of random allocation of treatments to the experimental units are illustrated in the following:

Consider an experiment with less than or up to 10 treatments. In this case, a 1-digit random number table can be used. The treatments are allotted a number each. The researcher picks up random numbers with replacement (i.e., a random number may get repeated) from the random number table until the number of replications of that treatment is exhausted.

For experiments with more than 10 treatments, a 2-digit random number table or a combination of two rows or columns of 1-digit random numbers can be used. Here each 2-digit random number is divided by the number of treatments, and the residual number is selected. When the residual is 00, the divisor number is selected. The digit 00 already occurring in the table is discarded. The digit 00 is discarded.

On small pieces of paper identical in shape and size, the numbers $1, 2, \dots, N$ are written. These are thoroughly mixed in a box, the papers are drawn one by one, and the numbers on the selected papers are random numbers. After each draw, the piece of paper is put back, and thorough mixing is performed again.

The random numbers may also be generated by computers.

Statistical Analysis

The data from CRD are examined by the method of one-way analysis of variance (ANOVA) for classification.

The analysis of data from CRD is performed using the linear fixed-effects model given as

$$y_{ij} = \mu + t_i + \varepsilon_{ij}, i = 1, 2, \dots, v; j = 1, 2, \dots, r_i;$$

where y_{ij} is the yield or response from the j th unit receiving the i th treatment, t_i is the fixed effect of the i th treatment, and ε_{ij} is random error effect. Suppose we are interested in knowing whether wheat can be grown in a particular agroclimatic situation. Then we will randomly select some varieties of wheat, from all possible varieties, for testing in an experiment. Here the effect of treatment is random. When the varieties are the only ones to be tested in an experiment, the effect of varieties (treatments) is fixed.

The experimental error is a random variable with mean zero and constant variance (σ^2). The experimental error is normally and independently distributed with mean zero and constant variance for every treatment.

Let $N = \sum r_i$ be the total number of experimental units, $\sum \sum y_{ij} = y \dots = G$ = grand total of all the observations, and $\sum y_{ij} = y = T_i$ = the total response from the experimental units receiving the i th treatment. Then,

$$\sum \sum (y_{ij} - \mu)^2 = \sum r_i (y_i \dots - \bar{y} \dots)^2 + \sum \sum (y_{ij} - \bar{y}_{i.})^2, i = 1, \dots, v; j = 1, 2, \dots, r_i,$$

that is, the total sum of squares is equal to the sum of the treatments sum of squares and the error sum of squares. This implies that the total variation can be partitioned into two components: between treatments and within treatments (experimental error).

Table 1 is an ANOVA table for CRD.

Table 1 Analysis of Variance for Completely Randomized Design

S_v	df	SS	MSS	Variance Ratio
Between treatments	$v - 1$	$TrSS$	$s_t^2 = TrSS / v - 1$	$F_t = s_t^2 / s_e^2$
Within treatments	$N - v$	$ErSS$	$s_e^2 = ErSS / N - v$	

Note: S_v sources of variation; df = degrees of freedom; SS = sum of squares; MSS = mean sum of squares (variance); $TrSS$ = treatments sum of squares; $ErSS$ = error sum of squares

Under the null hypothesis, $H_0 = t_1 = t_2 = \dots = t_v$; that is, all treatment means are equal, the statistic $F_t = s_t^2 / s_e^2$ follows the F distribution with $(v - 1)$ and $(N - v)$ degrees of freedom.

If $F(\text{observed}) \geq F(\text{expected})$ for the same df and at a specified level of significance, say $\alpha\%$, then the null hypothesis of equality of means is rejected at $\alpha\%$ level of significance.

If H_0 is rejected, then the pairwise comparison between the treatment means is made by using the critical difference (CD) test,

$$CD\alpha\% = SE_d \cdot t \text{ for error } df \text{ and } \alpha\% \text{ level of significance;}$$

where $SE_d = \sqrt{ErSS(1/r_i + 1/r_j)/(N - v)}$, SE_d stands for standard error of difference between means of two treatments and when $r_i = r_j$, $SE_d = -3pt \sqrt{2ErSS / \{r(N - v)\}}$.

If the difference between any two treatment means is greater than or equal to the critical difference, the treatment means are said to differ significantly.

The critical difference is also called the *least significant difference*.

Number of Replications

The number of replications required for an experiment is affected by the inherent variability and size of the experimental material, the number of treatments, and the degree of precision required. The minimum number of replications required to detect the specified differences between two treatment means at a specified level of significance is given by the t statistic at error df and $\alpha\%$ level of significance, $t = d / \{s_e \sqrt{2/r}\}$, where $d = \bar{X}_1 - \bar{X}_2$, $\bar{X}_1$ and $\bar{X}_2$ are treatment means with each treatment replicated r times, and s_e^2 is error variance.

Therefore,

$$r = 2t^2 s_e^2 / d^2.$$

It is observed that from 12 df onward, the values of t and F (for smaller error variance) decrease

considerably slowly, and so from empirical considerations the number of replications are so chosen as to provide about 12 *df* for error variance for the experiment.

Nonconformity to the Assumptions

When the assumptions are not realized, the researcher may apply one of the various transformations in order to bring improvements in assumptions. The researcher then may proceed with the usual ANOVA after the transformation. Some common types of transformations are described below.

Arc Sine Transformation

This transformation, also called *angular transformation*, is used for count data obtained from binomial distribution, such as success–failure, diseased–nondiseased, infested–noninfested, barren–nonbarren tillers, inoculated–noninoculated, male–female, dead–alive, and so forth.

The transformation is not applicable to percentages of carbohydrates, protein, profit, disease index, and so forth, which are not derived from count data. The transformation is not needed if nearly all the data lie between 30% and 70%. The transformation may be used when data range from 0% to 30% and beyond or from 100% to 70% and below. For transformation, $0/n$ and n/n should be taken as $1/4n$ and $(1-1/4n)$, respectively.

Square Root Transformation

The square root transformation is used for data from a Poisson distribution, that is, when data are counts of rare events such as number of defects or accidents, number of infested plants in a plot, insects caught on traps, or weeds per plot. The transformation consists of taking the square root of each observation before proceeding with the ANOVA in the usual manner.

Logarithmic Transformation

The logarithmic transformation is used when standard deviation is proportional to treatment means, that is, if the coefficient of variation is constant. The transformation achieves additivity. It is used for count data (large whole numbers) covering a wide range, such as number of insects per plant or number of egg masses. When zero occurs, 1 is added to it before transformation.

COMPUTERIZED ADAPTIVE TESTING

Adaptive testing, in general terms, is an assessment process in which the test items administered to examinees differ based on the examinees' responses to previous questions. Computerized adaptive testing uses computers to facilitate the *adaptive* aspects of the process and to automate scoring. This entry discusses historical perspectives, goals, psychometric and item selection approaches, and issues associated with adaptive testing in general and computerized adaptive testing in particular.

Historical Perspectives

Adaptive testing is not new. For over 100 years, examiners have asked questions and, depending on the response given, have chosen different questions for different examinees. Clinicians have long taken adaptive approaches. For example, since the advent of standardized intelligence testing, many such tests have used adaptive techniques. For both the 1916 edition of the Stanford–Binet and the 1939 edition of the Wechsler–Bellevue intelligence tests, the examiner chose a starting point and, if the examinee answered correctly, asked harder questions until a string of incorrect answers was provided. If the first answer was incorrect, an easier starting point was chosen.

While adaptive testing worked well logistically for individually administered tests, early group-administered adaptive tests faced logistical problems in the precomputerized administration era. Scoring each item and making continual routing decisions was a slow process. One alternative explored by William Angoff and Edith Huddleston in the 1950s was two-stage testing. An examinee would take a half-length test of

medium difficulty, that test was scored, and then the student would be routed to either an easier or a harder last half of the test. Another early adaptive testing routing mechanism involved use of a special marker that revealed invisible ink when used. Examinees would use their markers to indicate their responses. The marker would reveal the number of the next item they should answer. These and other approaches were cumbersome and never became popular.

Group-administered tests could not be administered adaptively with the necessary efficiency until the increasing availability of computer-based testing systems, circa 1970. At that time, research on computer-based testing proliferated. In 1974, Frederic Lord (inventor of the theoretical underpinnings of much of modern psychometric theory) suggested the field would benefit from researchers' getting together to share their ideas. David Weiss, a professor at the University of Minnesota, coordinated a series of three conferences on computerized adaptive testing in 1975, 1977, and 1979, bringing together some of the greatest thinkers in the field. These conferences energized the research community, which focused on the theoretical underpinnings and research necessary to develop and establish the psychometric quality of computerized adaptive tests.

The first large-scale computerized adaptive tests appeared circa 1985, including the U.S. Army's Computerized Adaptive Screening Test, the College Board's Computerized Placement Tests (the forerunner of today's Accuplacer), and the Computerized Adaptive Differential Ability Tests of the Psychological Corporation (now part of Pearson Education). Since that time, computerized adaptive tests have proliferated in all spheres of assessment.

Goals of Adaptive Testing

The choice of test content and administration mode should be based on the needs of a testing program. What is best for one program is not necessarily of importance for other programs. There are primarily three different needs that can be addressed well by adaptive testing: maximization of test reliability for a given testing time, minimization of individual testing time to achieve a particular reliability or decision accuracy, and the improvement of diagnostic information.

Maximization of Test Reliability

Maximizing reliability for a given testing time is possible because in conventional testing, many examinees spend time responding to items that are either trivially easy or extremely hard, and thus many items do

not contribute to our understanding of what the examinee knows and can do. If a student can consistently answer complex multiplication and division questions, there is little to be gained asking questions about single-digit addition. When multiple-choice items are used, students are sometimes correct when they randomly guess the answers to very difficult items. Thus, the answers to items that are very difficult for a student are worse than useless—they can be misleading.

An adaptive test maximizes reliability by eschewing items that are too difficult or too easy and instead using items of an appropriate difficulty. Typically this is done by ordering items by difficulty (usually using sophisticated statistical models such as Rasch scaling or the statistically more general item response theory) and administering more difficult items subsequent to correct responses and easier items after incorrect responses.

By tailoring the difficulty of the items administered dependent on prior examinee responses, a well-developed adaptive test can achieve the reliability of a conventional test with approximately one half to one third the items or, alternatively, can achieve a significantly higher reliability in a given amount of time. (However, testing time is unlikely to be reduced in proportion to the item reduction because very easy and very difficult items often require little time to answer correctly, or not try, respectively.)

Minimization of Testing Time

An alternative goal that can be addressed with adaptive testing is minimizing the testing time needed to achieve a fixed level of reliability. Items can be administered until the reliability of the test for a particular student, or the decision accuracy for a test that classifies examinees into groups (such as pass-fail), reaches an acceptable level. If the match between the proficiency of an examinee and the quality of the item pool is good (e.g., if there are many items that measure proficiency particularly well within a certain range of scores), few items will be required to determine an examinee's proficiency level with acceptable precision. Also, some examinees may be very consistent in their responses to items above or below their proficiency level—it might require fewer items to pinpoint their proficiency compared with people who are inconsistent.

Some approaches to adaptive testing depend on the assumption that items can be ordered along a single continuum of difficulty (also referred to as *unidimensionality*). One way to look at this is that the ordering of item difficulties is the same for all identifiable groups of examinees. In some areas of testing, this is not a reasonable assumption. For example, in a national test

of science for eighth-grade students, some students may have just studied life sciences and others may have completed a course in physical sciences. On average, life science questions will be easier for the first group than for the second, while physical science questions will be relatively easier for the second group. Sometimes the causes of differences in dimensionality may be more subtle, and so in many branches of testing, it is desirable not only to generate an overall total score but to produce a diagnostic profile of areas of strength and weakness, perhaps with the ultimate goal of pinpointing remediation efforts.

An examinee who had not recently studied physical science might get wrong a physical science item that students in general found easy (because they had recently studied the content). Subsequent items would be easier and that student might never receive the relatively difficult life sciences items that she or he could have answered correctly. That examinee might receive an underestimate of her or his true level of science proficiency.

One way to address this issue for multidimensional constructs would be to test each such construct separately. Another alternative would be to create groups of items balanced on content—*testlets*—and give examinees easier or harder testlets as the examinees progress through the test.

Improvement of Diagnostic Information

At this time, there is only one large-scale diagnostic testing program—the Dynamic Learning Maps (DLM) Alternate Assessment, which is used as the U.S. federally mandated accountability test for students with significant cognitive disabilities in about 20 states. DLM uses a psychometric approach called *diagnostic classification modeling* to identify the mastery profile of participating students. Content standards are broken down into smaller pieces referred to as *nodes* and are laid out in a map or network structure of precursor and successor skills. Loosely speaking, a student who masters one node is then presented with items for a successor node. For example, if one posits that successful addition of two-digit numbers with carrying requires the ability to add one-digit numbers with carrying, and an examinee answers a two-digit addition with carrying problem incorrectly, then the next problem asked might be a one-digit addition with carrying problem. Thus, in such an approach, expert knowledge of relationships within the content domain, perhaps validated through the gathering of many student responses to related items, drives the selection of the next item to be administered.

Psychometric Approaches to Scoring

There are four primary psychometric approaches that have been used to support item selection and scoring in adaptive testing: maximum likelihood item response theory, Bayesian item response theory, classical test theory, and decision theory. *Maximum likelihood item response theory* methods have long been used to estimate examinee proficiency. Whether they use the Rasch model, three-parameter logistic model, partial credit, or other item response theory models, fixed (previously estimated) item parameters make it fairly easy to estimate the proficiency level most likely to have led to the observed pattern of item scores.

Bayesian methods use information in addition to the examinee's pattern of responses and previously estimated item parameters to estimate examinee proficiency. Bayesian methods assume a population distribution of proficiency scores, often referred to as a *prior*, and use the unlikeness of an extreme score to moderate the estimate of the proficiency of examinees who achieved such extreme scores. Since examinees who have large positive or negative errors of measurement tend to get more extreme scores, Bayesian approaches tend to be more accurate (have smaller errors of measurement) than maximum likelihood approaches.

The essence of Bayesian methods for scoring is that the probabilities associated with the proficiency likelihood function are multiplied by the probabilities in the prior distribution, leading to a new, posterior, distribution. Once that posterior distribution is produced, there are two primary methods for choosing an examinee score. The first is called *modal estimation* or *maximum a posteriori*—pick the proficiency level that has the highest probability (probability density). The second method is called *expected a posteriori* and is essentially the mean of the posterior distribution.

Item response theory proficiency estimates have different psychometric characteristics from *classical test theory* approaches to scoring tests (based on the number of items answered correctly). The specifics of these differences are beyond the scope of this entry, but they have led some testing programs (especially ones in which some examinees take the test traditionally and some take it adaptively) to transform the item response theory proficiency estimate to an estimate of the number right that would have been obtained on a hypothetical base form of the test. From the examinee's item response theory—estimated proficiency and the set of item parameters for the base form items—the probability of a correct response can be estimated for each item, and the sum of those probabilities is used to estimate the number of items the examinee would have answered correctly.

Decision theory is a very different approach that can be used for tests that classify or categorize examinees, for example, into two groups, passing and failing. One approach that has been implemented for at least one national certification examination was developed by Charles Lewis and Kathleen Sheehan. Parallel testlets—sets of perhaps 10 items that cover the same content and are of about the same difficulty—were developed. After each testlet is administered, a decision is made to either stop testing and make a pass–fail decision or administer another testlet. The decision is based on whether the confidence interval around an examinee’s estimated score is entirely above or entirely below the proportion-correct cut score for a pass decision.

For example, consider a situation in which to pass, an examinee must demonstrate mastery of 60% of the items in a 100-item pool. We could ask all 100 items and see what percentage the examinee answers correctly. We could confidently end the test for an examinee who got the first 60 items correct—there is no way they are below the 60% requirement. In between those two approaches, it’s possible that a smaller number of questions could be given until one is statistically confident the examinee would get at least 60% of the items correct if we administered the entire test.

The Lewis–Sheehan decision theoretic approach is based on a branch of statistical theory called *Waldian sequential ratio testing*, in which after each sample of data, the confidence interval is calculated, and a

judgment is made, either that enough information is possessed to make a decision or that more data need to be gathered. Table 1 presents two simplified examples of examinees tested with multiple parallel 10-item testlets. The percent correct is boldfaced when it falls outside of the 99% confidence interval and a pass–fail decision is made.

The confidence interval in this example narrows as the sample of items (number of testlets administered) increases and gets closer to the full 100-item domain. Examinee 1 in Table 1 has a true domain percent correct close to the cut score of .60. Thus, it takes nine testlets to demonstrate Examinee 1 level of mastery is outside the required confidence interval. Examinee 2 has a true domain percent correct that is much higher than the cut score and thus demonstrates mastery with only two testlets.

Item Selection Approaches

Item selection can be subdivided into two pieces: selecting the first item (or set of items) and selecting all subsequent items. Selection of the first item is unique because for all other items, some current information about student proficiency (scores from previous items) is available. Several approaches can be used for selecting the first item. Everyone can get the same first item—one that is highly discriminating near the center of the score distribution—but such an approach would

Table 1 Record for Two Hypothetical Examinees Taking a Mastery Test Requiring 60% Correct on the Full-Length (100-Item) Test

After Testlet Number	Confidence Interval	Examinee 1		Examinee 2	
		Number Correct	Percent Correct	Number Correct	Percent Correct
1	.20–1.00	6	.60	9	.90
2	.34–.86	11	.55	19	.95
3	.40–.80	18	.60		
4	.34–.76	25	.63		
5	.37–.73	29	.58		
6	.50–.60	34	.57		
7	.52–.68	39	.56		
8	.54–.66	43	.54		
9	.56–.64	48	.53		
10	.60–.60				

quickly make that item nonsecure (i.e., it could be shared easily with future examinees). An alternative would be to randomly select from a set of items that discriminate well to the center of the score distribution. Yet, another approach might be to input some prior information (e.g., class grades or previous year's test scores) to help determine a starting point.

Once the first item is administered, several approaches exist for determining which items should be administered next to an examinee. There are two primary approaches to item selection for adaptive tests based on item response theory: maximum information and minimum posterior variance. With *maximum information* approaches, one selects the item that possesses the maximum amount of statistical information at the current estimated proficiency. Maximum information approaches are consistent with maximum likelihood item response theory scoring. *Minimum posterior variance* methods are appropriate for Bayesian scoring approaches. With this approach, the item is selected that, after scoring, will lead to the smallest variance of the posterior distribution, which is used to estimate the examinee's proficiency.

Most adaptive tests do not apply either of these item selection approaches in their purely statistical form. One reason to vary from these approaches is to ensure breadth of content coverage. Consider a physics test covering mechanics, electricity, magnetism, optics, waves, heat, and thermodynamics. If items are chosen solely by difficulty, some examinees might not receive any items about electricity and others might receive no items about optics. Despite items' being scaled on a national sample, any given examinee might have an idiosyncratic pattern of knowledge. Also, the sample of items in the pool might be missing topic coverage in certain difficulty ranges. A decision must be made to focus on item difficulty, content coverage, or some combination of the two.

Another consideration is item exposure. Since most adaptive test item pools are used for extended periods of time (months if not years), it is possible for items to become public knowledge. Sometimes this occurs as a result of concerted cheating efforts, sometimes just because examinees and potential examinees talk to each other. More complex item selection approaches, such as developed by Wim van der Linden, can be used to construct *on the fly* tests that meet a variety of predefined constraints on item selection.

Issues

This section addresses several issues associated with adaptive testing, including item pool requirements,

comparability of scores, and differential access to computers.

Item Pool Requirements

Item pool requirements for adaptive tests are typically more challenging than for traditional tests. With this proliferation, the psychometric advantages of adaptive testing have often been delivered, but logistical problems have been discovered. When stakes are high (e.g., admissions or licensure testing), test security is very important. The incentives for a marginal examinee to cheat are high, and this would invalidate test scores. It is still prohibitively expensive to arrange for a sufficient number of computers in a secure environment to test hundreds of thousands of examinees at one time, as some of the largest testing programs have traditionally done with paper tests. As an alternative, many computerized adaptive testing programs have moved from three to five administrations a year to administrations almost every day. This exposes items to large numbers of examinees who sometimes remember and share the items. Minimizing widespread cheating when exams are offered so frequently requires the creation of multiple item pools, an expensive undertaking, the cost of which is often passed on to examinees.

Another issue relates to the characteristics of the item pool required for adaptive testing. In a traditional norm-referenced test, most items are chosen so that about 60% of the examinees answer the item correctly. This difficulty level maximally differentiates people on a test in which everyone gets the same items. Thus, few very difficult items are needed, which is good since it is often difficult to write very difficult items that are neither ambiguous nor trivial. On an adaptive test, the most proficient examinees might all see the same very difficult items, and thus to maintain security, a higher percentage of such items are needed.

Comparability

Comparability of scores on computerized and traditional tests is a very important issue since some testing programs use both modes of administration and produce scores that are intended to be interchangeable. Many studies have been conducted to determine whether scores on computer-administered tests are comparable to those on traditional paper tests. Results of individual studies have varied, with some implying there is a general advantage to examinees who take tests on computer, others implying the advantage goes to examinees taking tests on paper, and some showing no statistically significant differences. Research design specialists recognize that individual studies contain

statistical sampling error that can obscure a general finding. A statistical approach called *meta-analysis* was developed to account for this. Several meta-analyses of the comparability of computerized tests and paper-and-pencil tests have been conducted. On average, they show at most very small differences unlikely to be of any consequence for most examinees. However, existing meta-analyses have not looked at potential score differences associated with the size of computer screens. Because of the relatively recent increasing availability of small screen handheld devices capable of administering tests, some researchers are concerned this could be of concern.

Differential Access to Computers

Many people are concerned that differential access to computers might disadvantage some examinees. While the number of studies looking at potential bias related to socioeconomic status, gender, ethnicity, or amount of computer experience is small, most recent studies have not found significant differences in student-age populations.

CONCOMITANT VARIABLE

It is not uncommon in designing research for an investigator to collect an array of variables representing characteristics on each observational unit. Some of these variables are central to the investigation, whereas others reflect preexisting differences in observational units and are not of interest per se. The latter are called *concomitant variables*, also referred to as *covariates*. Frequently in practice, these incidental variables represent undesired sources of variation influencing the dependent variable and are extraneous to the effects of manipulated (independent) variables, which are of primary interest. For designed experiments in which

observational units are randomized to treatment conditions, failure to account for concomitant variables can exert a systematic influence (or bias) on the different treatment conditions. Alternatively, concomitant variables can increase the error variance, thereby reducing the likelihood of detecting real differences among the groups. Given these potential disadvantages, an ideal design strategy is one that would minimize the effect of the unwanted sources of variation corresponding to these concomitant variables. In practice, two general approaches are used to control the effects of concomitant variables: (1) experimental control and (2) statistical control. An expected benefit of controlling the effects of concomitant variables by either or both of these approaches is a substantial reduction in error variance, resulting in greater precision for estimating the magnitude of treatment effects and increased statistical power.

Experimental Control

Controlling the effects of concomitant variables is generally desirable. In addition to random assignment of subjects to experimental conditions, methods can be applied to control these variables in the design phase of a study. One approach is to use a small number of concomitant variables as the inclusion criteria for selecting subjects to participate in the study (e.g., only eighth graders whose parents have at least a high school education). A second approach is to match subjects on a small number of concomitant variables and then randomly assign each matched subject to one of the treatment conditions. This requires that the concomitant variables are available prior to the formation of the treatment groups. *Blocking*, or *stratification*, as it is sometimes referred to, is another method of controlling concomitant variables in the design stage of a study. The basic premise is that subjects are sorted into relatively homogeneous blocks on the basis of levels of one or two concomitant variables. The experimental conditions are subsequently randomized within each stratum. Exerting experimental control through case selection, matching, and blocking can reduce experimental error, often resulting in improved statistical power to detect differences among the treatment groups. As an exclusive design strategy, the usefulness of any one of these three methods to control the effects of concomitant variables is limited, however. It is necessary to recognize that countless covariates, in addition to those used to block or match subjects, may be affecting the dependent variable and thus posing potential threats to drawing appropriate inferences regarding treatment veracity. In contrast, randomization to experimental conditions ensures that any idiosyncratic

differences among the groups are not systematic at the outset of the experiment. Random assignment does not guarantee that the groups are equivalent but rather that any observed differences are due only to chance.

Statistical Control

The effects of concomitant variables can be controlled statistically if they are included in the models used in analyzing the data, for instance by the use of socioeconomic status as a covariate in an analysis of covariance (ANCOVA). Statistical control for regression procedures such as ANCOVA means removing from the experimental error and from the treatment effect all extraneous variance associated with the concomitant variable. This reduction in error variance is proportional to the strength of the linear relationship between the dependent variable and the covariate and is often quite substantial. Consequently, statistical control is most advantageous in situations in which the concomitant variable and outcome have a strong linear dependency (e.g., a covariate that represents an earlier administration of the same instrument used to measure the dependent variable).

In quasi-experimental designs in which random assignment of observational units to treatments is not possible or potentially unethical, statistical control is achieved through adjusting the estimated treatment effect by controlling for preexisting group differences on the covariate. This adjustment can be striking, especially when the difference on the concomitant variable across intact treatment groups is dramatic. Like blocking or matching, using ANCOVA to equate groups on important covariates should not be viewed as a substitute for randomization. Control of all potential concomitant variables is not possible in quasi-experimental designs, which therefore are always subject to threats to internal validity from unidentified covariates. This occurs because uncontrolled covariates may be confounded with the effects of the treatment in a manner such that group comparisons are biased.

Benefits of Control

To the extent possible, research studies should be designed to control concomitant variables that are likely to systematically influence or mask the important relationships motivating the study. This can be accomplished by exerting experimental control through restricted selection procedures, randomization of subjects to experimental conditions, or stratification. In instances in which complete experimental control is not feasible or in conjunction with limited experimental control, statistical adjustments can be made through

regression procedures such as ANCOVA. In either case, advantages of instituting some level of control have positive benefits that include (a) a reduction in error variance and, hence, increased power and (b) a decrease in potential bias attributable to unaccounted concomitant variables.

CONCURRENT VALIDITY

Concurrent validity focuses on the extent to which scores on a new measure are related to scores from a criterion measure administered at the same time. It is a type of *criterion-related validity*. There are two forms of criterion-related validity: predictive validity and concurrent validity. *Predictive validity* uses the scores from the new measure to predict performance on a criterion measure administered at a later time, while *concurrent-based validity* is based on the accuracy of a test's ability to estimate performance on some other measure that could be taken at the same time, or concurrently.

Examples of contexts in which concurrent validity is relevant include the following:

- Scores on a written first aid exam are highly correlated with scores assigned by raters during a hands-on measure in which examinees demonstrate first aid procedures.
- Scores on a depression inventory are used to classify individuals who are simultaneously diagnosed by a licensed psychologist.

The primary motives for developing a new measure designed to tap the same construct of interest as an established measure are cost and convenience. A new measure that is shorter or less expensive but leads users to draw the same conclusions as a longer, more costly

measure is a highly desirable alternative. For example, to obtain the necessary information about examinee ability, decision makers might be able to administer a short written test to a large number of individuals at the same time instead of pricey, one-on-one performance evaluations that involve multiple ratings.

Before users make decisions based on scores from a new measure, they must have evidence that there is a close relationship between the scores of that measure and the performance on the criterion measure. This evidence can be obtained through a *concurrent validation study*. In a concurrent validation study, the new measure is administered to a sample of individuals that is representative of the group for which the measure will be used. An established criterion measure is administered to the sample at, or shortly after, the same time. The strength of the relationship between scores on the new measure and scores on the criterion measure indicates the degree of concurrent validity of the new measure.

The results of a concurrent validation study are typically evaluated in one of two ways, determined by the level of measurement of the scores from the two measures. When the scores on both the new measure and the criterion measure are *continuous*, the degree of concurrent validity is established via a *correlation coefficient*, usually the Pearson product-moment correlation coefficient. The correlation coefficient between the two sets of scores is also known as the *validity coefficient*. The validity coefficient can range from -1 to +1; coefficients close to 1 in absolute value indicate high concurrent validity of the new measure.

Figure 1 Scatterplot of Scores on a Written First Aid Exam and Scores Assigned by Raters During a Hands-On Demonstration Measure

In the example shown in Figure 1, the concurrent validity of the written exam is quite satisfactory because the scores on the written exam correlate highly with the scores assigned by the rater; individuals scoring well on the written measure were also rated as highly proficient and vice versa.

When the new measure and the criterion measure are both used to classify individuals, coefficients of classification agreement, which are variations of correlation coefficients for categorical data, are typically used. Evidence of high concurrent validity is obtained when the classifications based on the new measure tend to agree with classifications based on the criterion measure.

Table 1 displays hypothetical results of a concurrent validation study for categorical data. The concurrent validity of the depression inventory is high because the classification based on the new measure and the psychologist's professional judgment match in 91% of the cases.

When determining the concurrent validity of a new measure, the selection of a valid criterion measure is critical. Robert M. Thorndike has noted that criterion measures should ideally be relevant to the desired decisions, free from bias, and reliable. In other words, they should already possess all the ideal measurement conditions that the new measure should possess also. Specifically, criterion measures should be

- *relevant to the desired decisions*: Scores or classifications on the criterion measure should closely relate to, or represent, variation on the construct of interest. Previous validation studies and expert opinions should demonstrate the usefulness and appropriateness of the criterion for making inferences and decisions about the construct of interest.
- *free from bias*: Scores or classifications on the criterion measure should be free from bias, meaning that they should not be influenced by anything other than the construct of interest. Specifically, scores should not be impacted by personal characteristics of the individual, subjective opinions of a rater, or other measurement conditions.
- *reliable*: Scores or classifications on the criterion measure should be stable and replicable. That is, conclusions drawn about the construct of interest should not be clouded by inconsistent results across repeated administrations, alternative forms, or a lack of internal consistency of the criterion measure.

If the criterion measure against which the new measure is compared is invalid because it fails to meet these quality standards, the results of a concurrent validation study will be compromised. Put differently, the results from a concurrent validation study are only as useful as

Table I Cross-Classification of Classification From Inventory and Diagnosis by Psychologist

<i>Classification from Depression Inventory</i>	<i>Diagnosis by Psychologist</i>	
	<i>Depressed</i>	<i>Not Depressed</i>
Depressed	14	3
Not Depressed	7	86

the quality of the criterion measure that is used in it. Thus, it is key to select the criterion measure properly to ensure that a lack of a relationship between the scores from the new measure and the scores from the criterion measure is truly due to problems with the new measure and not to problems with the criterion measure.

Of course, the selection of an appropriate criterion measure will also be influenced by the availability or the cost of the measure. Thus, the practical limitations associated with criterion measurements that are inconvenient, expensive, or highly impractical to obtain may outweigh other desirable qualities of these measures.

CONFIDENCE INTERVALS

A confidence interval is an interval estimate of an unknown population parameter. It is constructed according to a random sample from the population and is always associated with a certain confidence level that is a probability, usually presented as a percentage. Commonly used confidence levels include 90%, 95%, and 99%. For instance, a confidence level of 95% indicates that 95% of the time the confidence intervals will contain the population parameter. A higher confidence level usually forces a confidence interval to be wider.

Confidence intervals have a long history. Using confidence intervals in statistical inference can be tracked back to the 1930s, and they are being used increasingly

in research, especially in recent medical research articles. Researchers and research organizations such as the American Psychological Association suggest that confidence intervals should always be reported because confidence intervals provide information on both significance of test and variability of estimation.

Interpretation

A confidence interval is a range in which an unknown population parameter is likely to be included. After independent samples are randomly selected from the same population, one confidence interval is constructed based on one sample with a certain confidence level. Together, all the confidence intervals should include the population parameter with the confidence level.

Suppose one is interested in estimating the proportion of bass among all types of fish in a lake. A 95% confidence interval for this proportion, [25%, 36%], is constructed on the basis of a random sample of fish in the lake. After more independent random samples of fish are selected from the lake, through the same procedure more confidence intervals are constructed. Together, all these confidence intervals will contain the true proportion of bass in the lake approximately 95% of the time.

The lower and upper boundaries of a confidence interval are called *lower confidence limit* and *upper confidence limit*, respectively. In the earlier example, 25% is the lower 95% confidence limit, and 36% is the upper 95% confidence limit.

Confidence Interval Versus Significance Test

A significance test can be achieved by constructing confidence intervals. One can conclude whether a test is significant based on the confidence intervals. Suppose the null hypothesis is that the population mean μ equals 0 and the predetermined significance level is α . Let I be the constructed $100(1 - \alpha)\%$ confidence interval for μ . If 0 is included in the interval I , then the null hypothesis is accepted; otherwise, it is rejected. For example, a researcher wants to test whether the result of an experiment has a mean 0 at 5% significance level. After the 95% confidence interval $[-.31, 0.21]$ is obtained, it can be concluded that the null hypothesis is accepted, because 0 is included in the confidence interval. If the 95% confidence interval is $[0.11, 0.61]$, it indicates that the mean is significantly different from 0.

For a predetermined significance level or confidence level, the ways of constructing confidence intervals are usually not unique. Shorter confidence intervals are usually better because they indicate greater power in the sense of significance test.

One-sided significance tests can be achieved by constructing one-sided confidence intervals. Suppose a researcher is interested in an alternative hypothesis that the population mean is larger than 0 at the significance level .025. The researcher will construct a one-sided confidence interval taking the form of $(-\infty, b]$ with some constant b . Note that the width of a one-sided confidence interval is infinity. Following the above example, the null hypothesis would be that the mean is less than or equal to 0 at the .025 level. If the 97.5% one-sided confidence interval is $(-\infty, 3.8]$, then the null hypothesis is accepted because 0 is included in the interval. If the 97.5% confidence interval is $(-\infty, -2.1]$ instead, then the null hypothesis is rejected because there is no overlap between $(-\infty, -2.1]$ and $[0, \infty)$.

Examples

Confidence Intervals for a Population Mean With Confidence Level 100 $(1 - \alpha)\%$

Confidence intervals for a population mean are constructed on the basis of the sample mean distribution.

The Population Follows a Normal Distribution With a Known Variance

σ^2 After a random sample of size N is selected from the population, one is able to calculate the sample mean $\bar{x}$, which is the average of all the observations. Thus the confidence interval is $[\bar{x} - z_{\alpha/2} \times \sigma / \sqrt{N}, \bar{x} + z_{\alpha/2} \times \sigma / \sqrt{N}]$ that is centered at $\bar{x}$ with half of the length $z_{\alpha/2} \times \sigma / \sqrt{N} = \frac{\alpha}{2}$ is the upper $\alpha/2$ quantile, meaning $P(z_{\alpha/2} \leq Z) = \alpha/2$. Here Z is a standard normal random variable. To find $z_{\alpha/2}$, one can either refer to the standard normal distribution table or use statistical software. Nowadays most of the statistical software, such as Excel, R, SAS, SPSS (an IBM company, formerly called PASW® Statistics), and Splus, have a simple command that will do the job. For commonly used confidence intervals, 90% confidence level corresponds to $Z_{0.05} = 1.645$, 95% corresponds to $Z_{0.025} = 1.96$, and 99% corresponds to $z_{0.005} = 2.56$.

The above confidence interval will shrink to a point if N goes to infinity. So the interval estimate turns into a point estimate. It can be interpreted as if the whole population is taken as the sample; the sample mean is actually the population mean.

The Population Follows a Normal Distribution With Unknown Variance.

Suppose a sample of size N is randomly selected from the population with observations $x_1, x_2, \dots, x_N$. Let

$\bar{x} = \sum_{i=1}^N x_i / N$. This is the sample mean. The sample variance is defined as $\sum_{i=1}^N (x_i - \bar{x})^2 / (N - 1)$, denoted by s^2 . Therefore the confidence interval is $[\bar{x} - t_{N-1, \alpha/2} \times s / \sqrt{N}, \bar{x} + t_{N-1, \alpha/2} \times s / \sqrt{N}]$. Here $t_{N-1, \alpha/2}$ is the upper $\alpha/2$ quantile, meaning $P(t_{N-1, \alpha/2} \leq T_{N-1}) = \alpha/2$ and T_{N-1} follows the t distribution with degree of freedom $N - 1$. Refer to the t -distribution table or use software to get $t_{N-1, \alpha/2}$. If N is greater than 30, one can use $z_{\alpha/2}$ instead of $t_{N-1, \alpha/2}$ in the confidence interval formula because there is little difference between them for large enough N .

As an example, the students' test scores in a class follow a normal distribution. One wants to construct a 95% confidence interval for the class average score based on an available random sample of size $N = 10$. The 10 scores are 69, 71, 77, 79, 82, 84, 80, 94, 78, and 67. The sample mean and the sample variance are 78.1 and 62.77, respectively. According the t -distribution table, $t_{9, 0.25} = 2.26$. The 95% confidence interval for the class average score is $[72.13, 84.07]$.

The Population Follows a General Distribution Other Than Normal Distribution

This is a common situation one might see in practice. After obtaining a random sample of size N from the population, where it is required that $N \geq 30$, the sample mean and the sample variance can be computed as in the previous subsections, denoted by $\bar{x}$ and s^2 , respectively. According to the central limit theorem, an approximate confidence interval can be expressed as $[\bar{x} - z_{\alpha/2} \times s / \sqrt{N}, \bar{x} + z_{\alpha/2} \times s / \sqrt{N}]$.

Confidence Interval for Difference of Two Population Means With Confidence Level 100 $(1 - \alpha)\%$

One will select a random sample from each population. Suppose the sample sizes are N_1 and N_2 . Denote the sample means by $\bar{x}_1$ and $\bar{x}_2$ and the sample variances by s_1^2 and s_2^2 , respectively, for the two samples. The confidence interval is $[\bar{x}_1 - \bar{x}_2 - z_{\alpha/2} \times \sqrt{s_1^2 / N_1 + s_2^2 / N_2}, \bar{x}_1 - \bar{x}_2 + z_{\alpha/2} \times \sqrt{s_1^2 / N_1 + s_2^2 / N_2}]$.

If one believes that the two population variances are about the same, the confidence interval will be $[\bar{x}_1 - \bar{x}_2 - t_{N_1+N_2-2, \alpha/2} \times s_p, \bar{x}_1 - \bar{x}_2 + t_{N_1+N_2-2, \alpha/2} \times s_p]$, where $s_p = \sqrt{(N_1+N_2)[(N_1-1)s_1^2 + (N_2-1)s_2^2] / [(N_1+N_2-2)N_1N_2]}$.

Continuing with the above example about the students' scores, call that class Class A: If one is interested in

comparing the average scores between Class A and another class, Class B, the confidence interval for the difference between the average class scores will be constructed. First, randomly select a group of students in Class B. Suppose the group size is Eight. These eight students' scores are 68, 79, 59, 76, 80, 89, 67, and 74. The sample mean is 74, and the sample variance is 86.56 for Class B. If Class A and Class B are believed to have different population variances, then the 95% confidence interval for the difference of the average scores is $[-4.03, 12.17]$ by the first formula provided in this subsection. If one believes these two classes have about the same population variance, then the 95% confidence interval will be changed to $[-4.47, 12.57]$ by the second formula.

Confidence Intervals for a Single Proportion and Difference of Two Proportions

Sometimes one may need to construct confidence intervals for a single unknown population proportion. Denote $\hat{p}$ the sample proportion, which can be obtained from a random sample from the population. The estimated standard error for the proportion is $se(\hat{p}) = \sqrt{\hat{p}(1-\hat{p})/N}$. Thus the confidence interval for the unknown proportion is $[\hat{p} - z_{\alpha/2} \times se(\hat{p}), \hat{p} + z_{\alpha/2} \times se(\hat{p})]$.

This confidence interval is constructed on the basis of the normal approximation (refer to the central limit theorem for the normal approximation). The normal approximation is not appropriate when the proportion is very close to 0 or 1. A rule of thumb is that when $N\hat{p} > 5$ and $N(1-\hat{p}) > 5$, usually the normal approximation works well.

For example, a doctor wants to construct a 99% confidence interval for the chance of having a certain disease by studying patients' x-ray slides. $N = 30$ x-ray slides are randomly selected, and the number of positive slides follows a distribution known as the binomial distribution. Suppose 12 of them are positive for the disease. Hence $\hat{p} = 12/30$, which is the sample proportion. Since $N\hat{p} = 12$ and $N(1-\hat{p}) = 18$ are both larger than 5, the confidence interval for the unknown proportion can be constructed using the normal approximation. The estimated standard error for $\hat{p}$ is 0.09. Thus the lower 99% confidence limit is 0.17 and the upper 99% confidence limit is 0.63. So the 99% confidence interval is $[0.17, 0.63]$.

The range of a proportion is between 0 and 1. But sometimes the constructed confidence interval for the proportion may exceed it. When this happens, one should truncate the confidence interval to make the lower confidence limit 0 or the upper confidence limit 1.

Since the binomial distribution is discrete, a correction for continuity of $0.5/N$ may be used to improve the performance of confidence intervals. The corrected upper limit is added by $0.5/N$, and the corrected lower limit is subtracted by $0.5/N$.

One can also construct confidence intervals for the proportion difference between two populations based on the normal approximation. Suppose two random samples are independently selected from the two populations, with sample sizes N_1 and N_2 and sample proportions $\hat{p}_1$ and $\hat{p}_2$, respectively. The estimated population proportion difference is the sample proportion difference, $\hat{p}_1 - \hat{p}_2$, and the estimated standard error for the proportion difference is $se(\hat{p}_1 - \hat{p}_2) = \sqrt{\hat{p}_1(1-\hat{p}_1)/N_1 + \hat{p}_2(1-\hat{p}_2)/N_2}$. The confidence interval for two-sample proportion difference is $[(\hat{p}_1 - \hat{p}_2) - z_{\alpha/2} \times se(\hat{p}_1 - \hat{p}_2), (\hat{p}_1 - \hat{p}_2) + z_{\alpha/2} \times se(\hat{p}_1 - \hat{p}_2)]$.

Similar to the normal approximation for a single proportion, the approximation for the proportion difference depends on sample sizes and sample proportions. The rule of thumb is that $N\hat{p}_1$, $N(1-\hat{p}_1)$, $N\hat{p}_2$, and $N(1-\hat{p}_2)$ should each be larger than 10.

Confidence Intervals for Odds Ratio

An *odds ratio* (OR) is a commonly used effect size for categorical outcomes, especially in health science, and is the ratio of the odds in Category 1 to the odds in Category 2. For example, one wants to find out the relationship between smoking and lung cancer. Two groups of subjects, smokers and nonsmokers, are recruited. After a few years' follow-ups, N_{11} subjects among the smokers are diagnosed with lung cancer and N_{21} subjects among the nonsmokers. There are N_{12} and N_{22} subjects who do not have lung cancer among the smokers and the nonsmokers, respectively. The *odds* of having lung cancer among the smokers and the nonsmokers are estimated as N_{11}/N_{12} and N_{21}/N_{22} , respectively. The OR of having lung cancer among the smokers compared with the nonsmokers is the ratio of the above two odds, which is

$$(N_{11}/N_{12}) / (N_{21}/N_{22}) = (N_{11}N_{22}) / (N_{21}N_{12}).$$

For a relatively large total sample size, $\ln(\text{OR})$ is approximated to a normal distribution, so the construction for the confidence interval for $\ln(\text{OR})$ is similar to that for the normal distribution. The standard error for $\ln(\text{OR})$ is defined as $se(\ln(\text{OR})) = \sqrt{1/N_{11} + 1/N_{12} + 1/N_{21} + 1/N_{22}}$. A 95% confidence interval for $\ln(\text{OR})$ is $[\ln(\text{OR}) - 1.96 \times se(\ln(\text{OR})), \ln(\text{OR}) + 1.96 \times se(\ln(\text{OR}))]$. As the exponential function is monotonic, there is one-to-one mapping between the OR and $\ln(\text{OR})$. Thus a

95% confidence interval for the OR is $[\exp(\ln(OR) - 1.96 \times se(\ln(OR))), \exp(\ln(OR) + 1.96 \times se(\ln(OR)))]$.

The confidence intervals for the OR are not symmetric about the estimated OR. But one can still tell the significance of the test on the basis of the corresponding confidence interval for the OR. For the above example, the null hypothesis is that there is no difference between smokers and nonsmokers in the development of lung cancer; that is, $OR = 1$. If 1 is included in the confidence interval, one should accept the null hypothesis; otherwise, one should reject it.

Confidence Intervals for Relative Risk

Another widely used concept in health care is *relative risk* (RR), which is the risk difference between two groups. *Risk* is defined as the chance of having a specific outcome among subjects in that group. Taking the above example, the risk of having lung cancer among smokers is estimated as $N_{11} / (N_{11} + N_{12})$, and the risk among nonsmokers is estimated as $N_{21} / (N_{21} + N_{22})$. The RR is the ratio of the above two risks, which is $[N_{11} / (N_{11} + N_{12})] / [N_{21} / (N_{21} + N_{22})]$.

Like the OR, the sampling distribution of $\ln(RR)$ is approximated to a normal distribution. The standard error for $\ln(RR)$ is $se(\ln(RR)) = \sqrt{1/N_{11} - 1/N_{11} + 1/N_{21} - 1/N_{22}}$. A 95% confidence interval for $\ln(RR)$ is

$$[\ln(RR) - 1.96 \times se(\ln(RR)), \ln(RR) + 1.96 \times se(\ln(RR))]$$

Thus the 95% confidence interval for the RR is $[\exp(\ln(RR) - 1.96 \times se(\ln(RR))), \exp(\ln(RR) + 1.96 \times se(\ln(RR)))]$.

The confidence intervals for the RRs are not symmetric about the estimated RR either. One can tell the significance of a test from the corresponding confidence interval for the RR. Usually the null hypothesis is that $RR = 1$, which means that the two groups have the same risk. For the above example, the null hypothesis would be that the risks of developing lung cancer among smokers and nonsmokers are equal. If 1 is included in the confidence interval, one may accept the null hypothesis. If not, the null hypothesis should be rejected.

Table 1 Lung Cancer Among Smokers and Nonsmokers

Smoking Status	Lung Cancer	No Lung Cancer	Total
Smokers	N_{11}	N_{12}	$N_{1.}$
Nonsmokers	N_{21}	N_{22}	$N_{2.}$
Total	$N_{.1}$	$N_{.2}$	N

Confidence Intervals for Variance

A confidence interval for unknown population variance can be constructed with the use of a central chi-square distribution. For a random sample with size N and sample variance s^2 , an approximate two-sided $100(1 - \alpha)\%$ confidence interval for population variance σ^2 is $[(N - 1)s^2 / \chi_{N-1}^2(\alpha/2), (N - 1)s^2 / \chi_{N-1}^2(1 - \alpha/2)]$. Here $\chi_{N-1}^2(\alpha/2)$ is at the upper $\alpha/2$ quantile satisfying the requirement that the probability that a central chi-square random variable with degree of freedom $N - 1$ is greater than $\chi_{N-1}^2(\alpha/2)$ is $\alpha/2$. Note that this confidence interval may not work well if the sample size is small or the distribution is far from normal.

Bootstrap Confidence Intervals

The bootstrap method provides an alternative way for constructing an interval to measure the accuracy of an estimate. It is especially useful when the usual confidence interval is hard or impossible to calculate. Suppose $s(x)$ is used to estimate an unknown population parameter θ based on a sample x of size N . A bootstrap confidence interval for the estimate can be constructed as follows. One randomly draws another sample x^* of the same size N with replacement from the original sample x . The estimate $s(x^*)$ based on x^* is called a *bootstrap replication* of the original estimate. Repeat the procedure for a large number of times, say 1,000 times. Then the α th quantile and the $(1 - \alpha)$ th quantile of the 1,000 bootstrap replications serve as the lower and upper limits of a $100(1 - 2\alpha)\%$ bootstrap confidence interval. Note that the interval obtained in this way may vary a little from time to time due to the randomness of bootstrap replications. Unlike the usual confidence interval, the bootstrap confidence interval does not require assumptions on the population distribution. Instead, it highly depends on the data x itself.

Simultaneous Confidence Intervals

Simultaneous confidence intervals are intervals for estimating two or more parameters at a time. For example, suppose μ_1 and μ_2 are the means of two different populations. One wants to find confidence intervals I_1 and I_2 simultaneously such that

$$P(\mu_1 \in I_1 \text{ and } \mu_2 \in I_2) = 1 - \alpha.$$

If the sample x_1 used to estimate μ_1 is independent of the sample x_2 for μ_2 , then I_1 and I_2 can be simply calculated as $100\sqrt{1 - \alpha}\%$ confidence intervals for μ_1 and μ_2 respectively.

The simultaneous confidence intervals I_1 and I_2 can be used to test whether μ_1 and μ_2 are equal. If I_1 and I_2 are nonoverlapped, then μ_1 and μ_2 are significantly different from each other at a level less than α .

Simultaneous confidence intervals can be generalized into a *confidence region* in the multidimensional parameter space, especially when the estimates for parameters are not independent. A $100(1 - \alpha)\%$ confidence region D for the parameter vector θ satisfies $P(\theta \in D) = 1 - \alpha$, where D does not need to be a product of simple intervals.

Links With Bayesian Intervals

A Bayesian interval, or *credible interval*, is derived from the posterior distribution of a population parameter. From a Bayesian point of view, the parameter θ can be regarded as a random quantity, which follows a distribution $P(\theta)$, known as the *prior distribution*. For each fixed θ , the data x are assumed to follow the conditional distribution $P(x|\theta)$, known as the *model*. Then Bayes's theorem can be applied on x to get the adjusted distribution $P(\theta|x)$ of θ , known as the *posterior distribution*, which is proportional to $P(x|\theta) \cdot P(\theta)$. A $1 - \alpha$ Bayesian interval I is an interval that satisfies $P(\theta \in I | x) = 1 - \alpha$ according to the posterior distribution. In order to guarantee the optimality or uniqueness of I , one may require that the values of the posterior density function inside I always be greater than any one outside I . In those cases, the Bayesian interval I is called the *highest posterior density region*. Unlike the usual confidence intervals, the level $1 - \alpha$ of a Bayesian interval I indicates the probability that the random θ falls into I .

CONFIDENTIALITY

Confidentiality is the condition of keeping a source's identity hidden from other receivers of information. When a source is confidential, both the identity of the source and the nature of the information is withheld from others unless the source gives permission for the information to be shared. The nature of confidential information is private between the source and receiver.

Confidentiality is often a condition of information exchange, especially when the nature of the information may be controversial, sensitive, or problematic. As a result, confidentiality is considered as a means to prevent the information from falling into unsupportive or critical hands, therefore protecting the sender and intended receiver. For example, a letter may be marked confidential if the sender intends it only for a specific receiver and does not want it to be read by any other person.

In research, confidentiality is often a requirement of institutional review boards (IRBs) when studying sensitive topics. For example, if a researcher was studying the mental health of a teenager, the IRB might require that the medical records be kept confidential, meaning the researcher cannot share specific information about the participant with any unapproved audience. This is done to protect the participant from a loss of privacy and the publicization of private medical information and to reduce the liability of both the researcher and the organization. When sensitive information is not confidential, there is a risk that outside audiences can obtain and use the data for unethical or retaliatory purposes. This both puts the participant at risk for retaliation and the organization at risk for not properly protecting the individual. As a result, confidentiality is often a required condition of scholarly research, one that protects all parties involved from the unethical or unauthorized use of information. The remainder of this entry discusses the relationship of confidentiality to anonymity, the principles of privacy that guide how researchers treat sources' information, and challenges to confidentiality.

Relationship to Anonymity

While often used synonymously with anonymity, confidentiality is different in that it requires that complete privacy be given to both the source and information. Whereas anonymity focuses specifically on the identity of the source, confidentiality requires that the information provided by the source also remain private.

For example, a study that promises anonymity to sources can still reveal information collected during the study. This may be in the publishing of the data set (without any source identifiers), quoting data in published work, or sharing data (without identifiers) with other researchers. This is often done in qualitative work based on texts from participants (such as social media posts, journal entries, or in-depth interviews). However, confidentiality requires researchers keep the data private. Even data that have the identifying information removed cannot be shared. Instead, researchers can publish syntheses or analyses of the data but cannot share any direct quotes or instances from the text. This is common in medical research where studies focus on analyzing trends or patterns, not specific instances, or cases.

Confidentiality is often considered a level beyond anonymity in that it requires extra work to keep both the source and information private. IRBs may require data be de-identified, meaning that all identifying information is removed, secured (locked to prevent unauthorized access), and destroyed after analysis. These steps help ensure the continued confidentiality of the data and the protection of participants.

Principles of Privacy

Confidentiality is offered in research to ensure privacy to the source and type of information gathered. Privacy is defined as the control over access to information, often an attribute granted by the owner or source of the information. Private information is concealed from unauthorized users, and only audiences who are granted approval can access and use it. When unauthorized audiences access information, it is considered a privacy violation—a condition that often diminishes the trust between the source and the audience.

There are four principles of privacy that guide how researchers should treat information from a source: (1) subjects should be informed of what data will be collected and how they will be used, (2) subjects should be able to determine the type of anonymity and confidentiality they are comfortable with prior to data collection, (3) researchers should inform subjects of any change to the status or use of data, and (4) subjects

should be able to change requests for privacy at any time in the research process.

Per most IRB and ethical requirements, subjects should know in advance what data researchers are gathering and how that data will inform studies. This also expands to include how data will be stored and how they will be potentially shared. This is often laid out in informed consent and required before a study is approved by an institution.

Allowing subjects to determine the type of anonymity and confidentiality they are comfortable with before their data are collected involves discussing how data will be stored and who will have access to them prior to the study. This also means answering participant questions and managing communication to ensure participants fully understand the nature of data collection. Participants should have the ability to judge or assess the data storage and usage, make recommendations, or request changes. If the researchers are unable to accommodate these requests, the subject should not face penalty for declining participation in the study.

Ongoing communication with the subject is necessary, particularly if there are occurrences of privacy violations or changes that may produce privacy violations. Subjects should be informed in a timely manner of any new personnel who may have access to the data as well as any changes to how it is stored.

Subjects may need to change their stipulations about privacy at any time in the research process because of changes in the research process or changes in what they are comfortable sharing. Researchers should also accommodate requests to destroy any existing data that subjects are no longer interested in sharing.

Each of these principles of privacy in research demonstrates the importance of clear communication between researchers and subjects when describing what type of data is collected and how it will be secured. Ongoing communication also helps document changes to data use as well as providing insights into the use and destruction processes.

Challenges to Confidentiality

While confidentiality is often an institutionalized requirement, there are instances where this challenges the nature and quality of research. For example, when data are confidential, researchers cannot provide direct quotes or examples when writing up results. Particularly in qualitative research, quotes are one method of proving the reliability of findings. However, in studies that guarantee confidentiality, quotes would not be allowed. Scholars eliminate the problem by adopting

quasi-confidential agreements, which more closely mimic anonymity and fail to provide complete privacy to the subject. This quasi-confidentiality is problematic in that it can reduce the trust between subjects and researchers and fails to uphold the four principles of privacy.

Confidentiality can also be challenged when researchers study topics that may involve legal ramifications. For example, scholars are often only granted access to communities engaging in illegal behaviors after promising confidentiality. However, law enforcement and justice departments may encourage or attempt to pressure researchers to reveal sources and information. While IRBs can protect researchers from these challenges, there are limits to this protection that place both the subjects' privacy and researchers' access at risk.

The effects of confidential information on the receiver also challenge the definitions and boundaries of this concept. When confidential information is particularly powerful or impactful, the receiver experiences changes in knowledge, attitude, emotion, or behavior as a response. Even when individuals carefully try to control this response, there is still a likely effect. The nature of this effect may reveal private information to others, inadvertently violating the confidential nature of the information.

For example, if an employee sends a confidential letter to a friend about the unethical practices of his employer, the receiver may change her engagement with or relationship to that organization. While the receiver may not reveal the nature of this confidential letter, onlookers may be able to guess about its nature by observing a change in the receiver's behavior. This change challenges the nature of confidentiality by partially—and unintentionally—revealing the topic.

Confidentiality also requires both the source and receiver of information to uphold the principles of privacy. For information to be truly confidential, neither party can reveal it to other receivers. If either party wants to share the information further, it requires mutual agreement to prevent a privacy violation. This mutual agreement may be difficult to achieve or overlooked by the source, who may consider themselves the most crucial decision maker because of the original ownership. Again, this may challenge the trust between the source and the receiver.

For scholars, confidentiality is both a tool and challenge to successful data collection, analysis, and storage. It is useful to motivate participants in the honest and open sharing of information, but it limits the use of this data and its presentation to other audiences. By upholding the four principles of privacy, researchers can keep information confidential and uphold ethical guidelines.

CONFIRMATORY FACTOR ANALYSIS

Research in the social and behavioral sciences often focuses on the measurement of unobservable, theoretical constructs such as ability, anxiety, depression, intelligence, and motivation. Constructs are identified by directly observable, manifest variables generally referred to as indicator variables (note that *indicator*, *observed*, and *manifest variables* are often used interchangeably). Indicator variables can take many forms, including individual items or one or more composite scores constructed across multiple items. Many indicators are available for measuring a construct, and each may differ in how reliably it measures the construct.

The choice of which indicator to use is based largely on availability. Traditional statistical techniques using single indicator measurement, such as regression analysis and path analysis, assume the indicator variable to be an error-free measure of the particular construct of interest. Such an assumption can lead to erroneous results.

Measurement error can be accounted for by the use of multiple indicators of each construct, thus creating a *latent variable*. This process is generally conducted in the framework of factor analysis, a multivariate statistical technique developed in the early to mid-1900s primarily for identifying and/or validating theoretical constructs. The general factor analysis model can be implemented in an exploratory or confirmatory framework. The exploratory framework, referred to as *exploratory factor analysis* (EFA), seeks to explain the relationships among the indicator variables through a given number of previously undefined latent variables. In contrast, the confirmatory framework, referred to as *confirmatory factor analysis* (CFA), uses latent variables to reproduce and test previously defined relationships between the indicator variables. The methods differ in their underlying purpose. Whereas EFA is a data-driven approach, CFA is a hypothesis driven approach requiring theoretically and/or empirically based insight into the relationships among the indicator variables. This insight is essential for establishing a starting point for the specification of a model to be tested. What follows is a more detailed, theoretical discussion of the CFA model, the process of implementing the CFA model, and the manner and settings in which the CFA model is most commonly implemented.

The Confirmatory Factor Analysis Model

The CFA model belongs to the larger family of modeling techniques referred to as *structural equation models*

Figure 1 Two-Factor Confirmatory Factor Analysis in LISREL Notation

(SEM). Structural equation models offer many advantages over traditional modeling techniques (although many traditional techniques, such as multiple regression, are considered special types of SEMs), among these the use of latent variables and the ability to model complex measurement error structures. The latter, measurement error, is not accounted for in the traditional techniques, and, as was previously mentioned, ignoring measurement error oftentimes leads to inaccurate results. Many different types of models can be put forth in the SEM framework, with the more elaborate models containing both of the SEM submodels: (a) the measurement model and (b) the structural model. The measurement model uses latent variables to explain variability that is shared by the indicator variables and variability that is unique to each indicator variable. The structural model, on the other hand, builds on the measurement model by analyzing the associations between the latent variables as direct causal effects.

The CFA model is considered a measurement model in which an unanalyzed association (covariance) between the latent variables is assumed to exist. Figure 1 displays a basic two-factor CFA model in LISREL notation. This diagram displays two latent variables, labeled with xi (pronounced ksi), ξ_1 and ξ_2 , each identified by three indicator variables (i.e., X_1 , X_2 , and X_3 for ξ_1 and X_4 , X_5 , and X_6 for ξ_2). The single-headed arrows pointing from the latent variables to each of the indicator variables represent factor loadings or pattern coefficients, generally interpreted as regression coefficients, labeled with lambda as λ_{11} , λ_{21} , λ_{31} , λ_{42} , λ_{52} , and λ_{62} and signifying the direction and magnitude of the relationship between each indicator and latent variable. For instance, λ_{21} represents the direction and magnitude of the relationship between latent variable one (ξ_1) and indicator variable two (X_2). These coefficients can be reported in standardized or unstandardized form. The double-headed arrow between the latent variables, labeled as ϕ_{21} (phi), represents an unanalyzed covariance or correlation between the latent variables. This value signifies the direction and magnitude of the relationship between the latent variables. Variability in the indicator variables not attributable to the latent variable, termed measurement error, is represented by the single-headed arrows pointing toward the indicator variables from each of the measurement error terms, labeled with delta as δ_1 , δ_2 , δ_3 , δ_4 , δ_5 , and δ_6 . These are essentially latent variables assumed to be independent of each other and of the latent variables ξ_1 and ξ_2 .

The CFA model depicted in Figure 1 can be represented in equation form as follows:

$$\begin{aligned}
x_1 &= \lambda_{11}\xi_1 + \delta_1 \\
x_2 &= \lambda_{21}\xi_1 + \delta_2 \\
x_3 &= \lambda_{31}\xi_1 + \delta_3 \\
x_4 &= \lambda_{42}\xi_2 + \delta_4 \\
x_5 &= \lambda_{52}\xi_2 + \delta_5 \\
x_6 &= \lambda_{62}\xi_2 + \delta_6
\end{aligned}$$

These equations can be written in more compact form by using matrix notation:

$$x = \Lambda\xi + \delta,$$

where x is a $q \times 1$ vector of observed indicator variables (where q is the number of observed indicator variables), Λ is a $q \times n$ matrix of regression coefficients relating the indicators to the latent variables (where n is the number of latent variables), ξ is an $n \times 1$ vector of latent variables, and δ is a $q \times 1$ vector of measurement errors that are assumed to be independent of each other. The equation above written in matrix notation is recognized as the measurement model in a general structural equation model.

The path diagram in Figure 1 depicts an ideal CFA model. The terms *simple structure* and *unidimensional measurement* are used in the general factor analysis framework to signify a model that meets two conditions: (1) Each latent variable is defined by a subset of indicator variables which are strong indicators of that latent variable, and (2) each indicator variable is strongly related to a single latent variable and weakly related to the other latent variable(s). In general, the second condition is met in the CFA framework with the initial specification of the model relating each indicator variable to a single latent variable. However, subsequent testing of the initial CFA model may reveal the presence of an indicator variable that is strongly related to multiple latent variables. This is a form of multidimensional measurement represented in the model by a path between an indicator variable and the particular latent variable it is related to. This is referred to as a *cross-loading* (not included in Figure 1).

Researchers using EFA often encounter cross-loadings because models are not specified in advance. Simple structure can be obtained in EFA through the implementation of a rotation method. However, a rotated factor solution does not remove the presence of cross-loadings, particularly when the rotation method allows for correlated factors (i.e., oblique rotation). As previously mentioned, specifying the model in advance provides the researcher flexibility in testing if the inclusion of one or more cross-loadings results in a better explanation of the relationships in

the observed data. Literature on this topic reveals the presence of conflicting points of view. In certain instances, it may be plausible for an indicator to load on multiple factors. However, specifying unidimensional models has many advantages, including but not limited to providing a clearer interpretation of the model and a more precise assessment of convergent and discriminant validity than multidimensional models do.

Multidimensional measurement is not limited to situations involving cross-loadings. Models are also considered multidimensional when measurement errors are not independent of one another. In such models, measurement errors can be specified to correlate. Correlating measurement errors allows for hypotheses to be tested regarding shared variance that is not due to the underlying factors. Specifying the presence of correlated measurement errors in a CFA model should be based primarily on model parsimony and, perhaps most important, on substantive considerations.

Conducting a Confirmatory Factor Analysis

Structural equation modeling is also referred to as *covariance structure analysis* because the covariance matrix is the focus of the analysis. The general null hypothesis to be tested in CFA is

$$\Sigma = \Sigma(\Theta),$$

where Σ is the population covariance matrix, estimated by the sample covariance matrix S , and $\Sigma(\Theta)$ is the model-implied covariance matrix, estimated by $\hat{\Sigma}(\hat{\Theta})$. Researchers using CFA seek to specify a model that most precisely explains the relationships among the variables in the original data set. In other words, the model put forth by the researcher reproduces or fits the observed sample data to some degree. The more precise the fit of the model to the data, the smaller the difference between the sample covariance matrix, S , and the model-implied covariance matrix, $\hat{\Sigma}(\hat{\Theta})$. To evaluate the null hypothesis in this manner, a sequence of steps common to implementing structural equation models must be followed.

The first step, often considered the most challenging, requires the researcher to specify the model to be evaluated. To do so, researchers must use all available information (e.g., theory, previous research) to postulate the relationships they expect to find in the observed data prior to the data collection process. Postulating a model may also involve the use of EFA as an initial step in developing the model. Different data sets must be used when this approach is taken because EFA results are subject to capitalizing on chance. Following an EFA

with a CFA on the same data set may compound the capitalization-on-chance problem and lead to inaccurate conclusions based on the results.

Next, the researcher must determine whether the model is identified. At this stage, the research must determine whether, based on the sample covariance matrix, S , and the model-implied covariance matrix, $\Sigma(\Theta)$, a unique estimate of each unknown parameter in the model can be identified. The model is identified if the number of parameters to be estimated is less than or equal to the number of unique elements in the variance-covariance matrix used in the analysis. This is the case when the degrees of freedom for the model are greater than or equal to 0. In addition, a metric must be defined for every latent variable, including the measurement errors. This is typically done by setting the metric of each latent variable equal to the metric of one of its indicators (i.e., fixing the loading between indicator and its respective latent variable to 1) but can also be done by setting the variance of each latent variable equal to 1.

The process of model estimation in CFA (and SEM, in general) involves the use of a fitting function such as generalized least squares or maximum likelihood (ML) to obtain estimates of model parameters that minimize the discrepancy between the sample covariance matrix, S , and the model implied covariance matrix, $\Sigma(\Theta)$. ML estimation is the most commonly used method of model estimation. All the major software packages (e.g., AMOS, EQS, LISREL, MPlus) available for posing and testing CFA models provide a form of ML estimation. This method has also been extended to address issues that are common in applied settings (e.g., nonnormal data, missing data), making CFA applicable to a wide variety of data types.

Various goodness-of-fit indices are available for determining whether the sample covariance matrix, S , and the model implied covariance matrix, $\Sigma(\Theta)$, are sufficiently equal to deem the model meaningful. Many of these indices are derived directly from the ML fitting function. The primary index is the chi-square. Because of the problems inherent with this index (e.g., inflated by sample size), assessing the fit of a model requires the use of multiple indices from the three broadly defined categories of indices: (1) absolute fit, (2) parsimony correction, and (3) comparative fit. The extensive research on fit indices has fueled the debate and answered many questions as to which are useful and what cutoff values should be adopted for determining adequate model fit in a variety of situations. Research has indicated that fit indices from each of these categories provide pertinent information and should be used in unison when conducting a CFA.

Even for a well-fitting model, further respecification may be required because goodness-of-fit indices evaluate the model globally. Obviously, a model that fits the data poorly requires reconsideration of the nature of the relationships specified in the model. Models that fit the data at an acceptable level, however, may fail to explain all the relationships in the variance-covariance matrix adequately. The process of model respecification involves a careful examination of areas in which the model may not explain relationships adequately. A careful inspection of the residual variance-covariance matrix, which represents the difference between the sample variance-covariance matrix, S , and the model-implied variance-covariance matrix, $\Sigma(\Theta)$, can reveal poorly explained relationships. Modification indices can also be used for determining what part of a model should be respecified. The *Lagrange multiplier test* can be used to test whether certain relationships should be included in the model, and the *Wald test* can be used to determine whether certain relationships should be excluded from the model. Last, parameter estimates themselves should be carefully examined in terms of practical (i.e., interpretability) as well as statistical significance.

Following the aforementioned steps is common practice in the application of CFA models in research. The final step, respecification of the model, can uncover statistically equivalent versions of the original CFA model found to provide the best fit. These models are equivalent in the sense that they each explain the original data equally well. While many of the equivalent models that can be generated will not offer theoretically plausible alternatives to the original model, there will likely be a competing model that must be considered before a final model is chosen. The complex decision of which model offers the best fit statistically and theoretically can be made easier by a researcher with a strong grasp of the theory underlying the original model put forth.

Applications of Confirmatory Factor Analysis Models

CFA has many applications in the practical realm. The following section discusses some of the more common uses of the CFA model.

Scale Development

CFA can be particularly useful in the process of developing a scale for tests or survey instruments. Developing such an instrument requires a strong understanding of the theoretical constructs that are to

be evaluated by the instrument. CFA procedures can be used to verify the underlying structure of the instrument and to quantify the relationship between each item and the construct it was designed to measure, as well as quantify the relationships between the constructs themselves. In addition, CFA can be used to aid in the process of devising a scoring system as well as evaluating the reliability of an instrument. Recent advances in the use of CFA with categorical data also make it an attractive alternative to the item response theory model for investigating issues such as measurement invariance.

Validity of Theoretical Constructs

CFA is a particularly effective tool for examining the validity of theoretical constructs. One of the most common approaches to testing validity of theoretical constructs is through the multitrait-multimethod (MTMM) design, in which multiple traits (i.e., constructs) are assessed through multiple methods. The MTMM design is particularly effective in evaluating *convergent validity* (i.e., strong relations among different indicators, collected via different methods, of the same construct) and *discriminant validity* (i.e., weak relations among different indicators, collected via different methods, of distinct constructs). The MTMM design can also be used to determine whether a *method effect* (i.e., strong relations among different indicators of distinct constructs, collected via the same method) is present.

Measurement Invariance

CFA models are commonly used in the assessment of measurement invariance and population heterogeneity. By definition, *measurement invariance* refers to the degree to which measurement models generalize across different groups (e.g., males vs. females, native vs. nonnative English speakers) as well as how a measurement instrument generalizes across time. To assess measurement invariance, CFA models can be specified as either *multiple group models* or *multiple indicator-multiple cause (MIMIC) models*. While these models are considered interchangeable, there are advantages to employing the multiple group approach. In the multiple group approach, tests of invariance across a greater number of parameters can be conducted. The MIMIC model tests for differences in intercept and factor means, essentially providing information about which covariates have direct effects in order to determine what grouping variables might be important in a multiple group analysis. A multiple group model, on the other hand, offers tests for differences in intercept

and factor means as well as tests of other parameters such as the factor loadings, error variances and covariances, factor means, and factor covariances. The caveat of employing a multiple group model, however, lies in the necessity of having a sufficiently large sample size for each group, as well as addressing the difficulties that arise in analyses involving many groups. The MIMIC model is a more practical approach with smaller samples.

Higher Order Models

The CFA models presented to this point have been first-order models. These first-order models include the specification of all necessary parameters excluding the assumed relationship between the factors themselves. This suggests that even though a relationship between the factors is assumed to exist, the nature of that relationship is “unanalyzed” or not specified in the initial model. Higher order models are used in cases in which the relationship between the factors is of interest. A higher order model focuses on examining the relationship between the first-order factors, resulting in a distinction between variability shared by the first-order factors and variability left unexplained. The process of conducting a CFA with second-order factors is essentially the same as the process of testing a CFA with first-order factors.

Summary

CFA models are used in a variety of contexts. Their popularity results from the need in applied research for formal tests of theories involving unobservable latent constructs. In general, the popularity of SEM and its use in testing causal relationships among constructs will require sound measurement of the latent constructs through the CFA approach.

CONFIRMATORY RESEARCH

Confirmatory research is the complex process of data collection, analysis, and interpretation that aims at testing *a priori* hypotheses, formulated before the beginning of the measurement and derived from a theory or from the results of previous studies.

Confirmatory research starts from the identification of a series of alternative assumptions concerning some topics of interest, followed by the development of a research design to test a series of hypotheses through data gathering and analysis, which end with the proposition of inferences. In empirical research, based on inductive and deductive logic, the alternative hypotheses cannot be proven to be true but can only be refuted or not refuted. Failing to refute one or more of the hypotheses leads researchers to gain some measure of confidence in the validity of those hypotheses.

The confirmatory approach is based on the design of hypotheses about the relationships between a set of variables subjected to empirical control. Researchers can identify, select, and connect the variables based on their previous knowledge. In this way, before the beginning of the research design, researchers can evaluate whether the hypotheses can fit with the data available in order to create data analysis models to be submitted to statistical inference techniques to reach the generalization of the results beyond the sample examined.

Confirmatory analysis can be defined as an ending point, in which the strong theoretical structuring of the hypotheses derives from a robust knowledge of the field of study and allows to create reasonings that reproduce the cognitive questions of the research as an interconnection of relationships between the variables (e.g., if x influences y and to what extent, if x and y generate z or vice versa). This approach does not aim at describing a phenomenon but seeks to interpret its causes, effects, influences, and possible developments, through a detailed modeling of the variables involved and of the structure that dominates the relationships between them. This process does not involve the creativity or imagination but requires the application of all the knowledge and experience of researchers. The most significant outcome of confirmatory research is the systematization of the hypotheses and the detection of the structure of the links between variables, methods, and detectable trends.

After briefly reviewing the origins of confirmatory research, this entry discusses the confirmatory research approach with regard to research design, methodological choices and data analysis techniques.

The Roots of Confirmatory Research

The diffusion of confirmatory research stems from the introduction of nomothetic-idiographic dichotomy, advanced by Immanuel Kant and Neo-Kantian philosopher Wilhelm Windelband at the end of the 19th century to describe two distinct approaches to knowledge and intellectual perspectives. The nomothetic approach is based on the tendency to generalize and is employed commonly in natural science to find laws that describe phenomena and explain types or categories of objective events and features. The idiographic approach seeks not to generate hypotheses but examines a data set in-depth to look, after the exploration, for the potential relations between variables as they occur in each context.

Confirmatory research has been deepened with the advent of Positivism, a philosophical current of thought introduced in Europe in the second half of the 19th century, which focuses on the research for scientific progress in natural science. Positivists advocate the search for facts and causes of social phenomena with little regard for subjective states and employ standardized, structured, intrusive techniques and controlled measurement.

Confirmatory Research in the Research Design

The confirmatory approach is carried out in the early stages of the research design, in which researchers establish possible cognitive purposes with respect to their cognitive objectives. If these purposes relate to a known field and aim at investigating a concept already operationalized in previous studies, then it is possible to formulate some starting hypotheses. The development of hypotheses will guide the entire research process (the subsequent choice of the methodological approach, of the technique for data analysis, of the modality of administration), targeted at detecting the possible relationships, including causal effects, that link the variables under investigation. The operationalization of variables is a series of operations for the translation of scientific concepts into observable, executable, and communicable procedures. In social science, the technical conception of operationalization is obtained through the design of indicators and variables.

Exploratory Versus Confirmatory Research

The explicit hypotheses tested with confirmatory research are not the result of the intellectual effort of researchers but are gained often through exploratory research. The exploratory approach can be used to generate hypotheses that later can be tested with

confirmatory approaches. Confirmatory research is usually experimental, whereas exploratory research may be either experimental or observational. The aim of exploratory research is to gain new insights, from which new hypotheses might be developed. On one hand, the exploratory analysis is a necessary starting point for research, but it cannot completely exhaust the cognitive needs that guide the development of a study. On the other hand, if an exploratory survey does not produce indications and institutions for quantitative measurement, then confirmatory analysis cannot even begin.

The goal of confirmatory research is to minimize the probability of a Type I error, which is to reject the null hypothesis when in fact it is true. The goal of exploratory research is to search for hypotheses and, thus, to minimize the probability of committing a Type II error, which is failing to reject the null hypothesis when in fact it is false.

Exploratory and confirmatory research can be positioned on a continuum, which ranges from purely exploratory research, in which the hypothesis is found in the data, to purely confirmatory research, in which the entire research design is explicated before the beginning of the analysis.

The differences between confirmatory and exploratory research are related to the distinct viewpoints adopted at the beginning of the research design. They can have different initial outcomes and can depend on the clarity of the research questions (i.e., vague questions or the need to analyze immaterial concepts require exploratory approach) or on the preexisting beliefs of researchers (i.e., when results of previous research are ambiguous, researchers who believe in the presence of an effect can encourage exploration). In the confirmatory approach, researchers preregister their studies; in this way, data collection and data analyses are not based on exploration and the corresponding statistics are sound in the sense that they are used for their intended purpose. Much empirical research is situated between these two extremes, although for any specific study it is not possible to find the exact location.

In both approaches, there is the need to formulate hypotheses to identify the focus of the attention, which will be more precise in the confirmatory investigation and less detailed in exploratory research. If the hypotheses are lacking, semistructured or nonstructured interviews (techniques employed in exploratory research) can be conducted unreliably and produce poor results; similarly, a structured questionnaire (employed mostly for confirmatory research) can become an ungovernable string of questions.

The confusion between exploratory and confirmatory research can compromise the validity of an empirical research. Exploration is an essential component of

science and is key to new discoveries and scientific progress. Hence, in the first stage of a research program, researchers should feel free to conduct exploratory studies, which cannot be presented as strong evidence in favor of a particular hypothesis. The focus of exploratory research is to describe interesting aspects of data, to discover tentative and relevant findings, to propose insights for future studies, which may confirm or disconfirm the initial exploratory results. In the second stage of a research design, the confirmatory approach can be required. In confirmatory research, the hypotheses are clearly stated in the introductory phases and the causal inferences evaluating those hypotheses are in the report of results. The findings obtained in confirmatory research concern a set of complex decisions that are undertaken before researchers collect and analyze the data.

Exploratory and confirmatory approaches are two different ways of conceiving the entire research design and the cognitive questions that generate it, between the need for exploration and the need for structuring. They are not opposite, but complementary and neither confirmatory nor exploratory approach can be considered as a generally valid method that automatically guarantees the achievement of reliable results. The choice of the most appropriate approach should be evaluated carefully each time in the given context and should be selected by balancing the type of phenomenon studied and the characteristics of the research questions. In most cases, the solution can be found in the integration of both the approaches, in a two-step procedure in which data collection is subdivided into two subsequent stages, with different research objectives and techniques, or in which data collection is split in an exploratory and a confirmatory subset.

Complexity in Methodological Choices

Even if researchers are guided by a solid theoretical framework, it is not possible to select confirmatory research to reach generalizable causal inferences automatically. The choices made by researchers play an important role and should be made explicitly to verify the formal and substantial suitability of the different alternatives.

An important requirement to make a real contribution to the advancement of knowledge and scientific research is to select the most right approach based on the nature and on the essence of the investigated phenomena and reflecting the kind of cognitive objectives pursued.

However, in given contexts, the theoretical guide in the design of research objectives can play a relevant role, whereas in other situations, the theoretical

contributions are not sufficient or can prevent the goodness of research design. Some topics are indeed more explored than others, the theory is more developed, and hypotheses can be constructed to submit to more structured empirical verification. In these cases, the research can be confirmatory and can strive to obtain confirmation of something (a phenomenon or a relationship between two events) that can be already partially established. This investigation can check whether a hypothesis that has reached a good degree of validation (or which is not yet falsified) confirms its validity by subjecting it to the test of an empirical referent differently located spatially and/or temporally. If confirmatory investigations prioritize the needs of justification, in other situations the possibility of discovery can be privileged. When a phenomenon is poorly known, not sufficiently explored empirically, or examined by little research, it is advisable to carry out an exploratory investigation.

The advantage of confirmatory research is that the result can be more significant. In confirmatory research, it is hard to show that a certain result is generalizable beyond the data set. When this happens, the findings of confirmatory research can reduce the probability of reporting erroneously a coincidental result as meaningful.

The Quantitative Approach and the Most Common Techniques

After the accomplishment of the preliminary steps of research design, data analysis can be carried out by using a plurality of statistical procedures selected in relation to the purposes of the research (exploratory or confirmatory, nomothetic or idiographic, descriptive or inferential) and the nature of the data collected (measurement levels).

In line with the key principles of confirmatory approach, research based on quantitative approach seeks to be objective, detached from the data (according to an external perspective, in which the researcher does not get involved), oriented to verification, inferential and hypothetical, deductive. Quantitative research is result-oriented, reliable, replicable, generalizable, particularistic and assumes the existence of a stable reality that can be easily measured. For this reason, quantitative methodology is the most common solution employed in confirmatory research.

Quantitative analysis techniques can be based on bivariate linear regression (between two variables) or multiple linear regression (between three or more variables) in which some hypotheses are formulated on the relationships and influences between cardinal (or numerical) variables, represented by statuses on a property in numeric form (e.g., age, income, costs, height).

In particular, factor analysis, a multivariate analysis technique, can be confirmatory and exploratory. The objective of factor analysis is to represent simultaneously a set of variables and/or cases in a data matrix in order to achieve an effective synthesis of the data, by transforming mathematically the numeric variables related to each other into a smaller number of new independent constructs (called *factors*). In line with the exploratory-confirmatory dichotomy, there are two types of factor analysis, carried out in two different steps and at two different times of research design: (1) exploratory factor analysis, used to specify the dimensions before the purification of the variables to give birth to factors; (2) confirmatory factor analysis, in which the dimensions are chosen before the analysis (through the results of preliminary exploratory analysis), which aims exclusively at confirming them. It occurs after a first purification of the variables.

As well as for the complex methodological choices related to exploratory and/or confirmatory research, the multimethods approach (the integrated use of different techniques) and the mixed methods approach (the integrated use of quantitative and qualitative approach) can be the most suitable solution for a reliable research.

CONFOUNDING

Quantitative research is typically designed to demonstrate a relationship between an independent variable that a researcher has manipulated (e.g., receiving a treatment or not receiving a treatment) and dependent variable. If, though, the true relationship is between

some other variable and the dependent variable, then confounding has occurred. Confounding can only occur when two variables systematically covary. Researchers are often interested in examining whether there is a relationship between two or more variables. Understanding the relationship between or among variables, including whether those relationships are causal, can be complicated when an independent or predictor variable covaries with a variable other than the dependent variable. When a variable systematically varies with the independent variable, the confounding variable provides an explanation other than the independent variable for changes in the dependent variable.

Confounds in Correlational Designs

Confounding variables are at the heart of the third-variable problem in correlational studies. In a correlational study, researchers examine the relationship between two variables. Even if two variables are correlated, it is possible that a third, confounding variable is responsible for the apparent relationship between the two variables. For example, if there were a correlation between ice cream consumption and homicide rates, it would be a mistake to assume that eating ice cream causes homicidal rages or that murderers seek frozen treats after killing. Instead, a third variable—heat—is likely responsible for both increases in ice cream consumption and homicides (given that heat has been shown to increase aggression). Although one can attempt to identify and statistically control for confounding variables in correlational studies, it is always possible that an unidentified confound is producing the correlation.

Confounds in Quasi-Experimental and Experimental Designs

The goal of quasi-experimental and experimental studies is to examine the effect of some treatment on an outcome variable. When the treatment systematically varies with some other variable, the variables are confounded, meaning that the treatment effect is comingled with the effects of other variables. Common sources of confounding include history, maturation, instrumentation, and participant selection. History confounds may arise in quasi-experimental designs when an event that affects the outcome variable happens between pretreatment measurement of the outcome variable and its posttreatment measurement. The events that occur between pre- and posttest measurement, rather than the treatment, may be responsible for changes in the dependent variable. Maturation confounds are a concern if participants could have developed—cognitively, physically, and

emotionally—between pre- and posttest measurement of the outcome variable. Instrumentation confounds occur when different instruments are used to measure the dependent variable at pre- and posttest or when the instrument used to collect the observation deteriorates (e.g., a spring loosens or wears out on a key used for responding in a timed task). Selection confounds may be present if the participants are not randomly assigned to treatments (e.g., use of intact groups, participants self-select into treatment groups). In each case, the confound provides an alternative explanation—an event, participant development, instrumentation changes, and preexisting differences between groups—for any treatment effects on the outcome variable.

Even though the point of conducting an experiment is to control the effects of potentially confounding variables through the manipulation of an independent variable and random assignment of participants to experimental conditions, it is possible for experiments to contain confounds. An experiment may contain a confound because the experimenter intentionally or unintentionally manipulated two constructs in a way that caused their systematic variation. The Illinois Pilot Program on sequential, double-blind procedures provides an example of an experiment that suffers from a confound. In this study commissioned by the Illinois legislature, eyewitness identification procedures conducted in several Illinois police departments were randomly assigned to one of two conditions. For the sequential, double-blind condition, administrators who were blind to the suspect's identity showed members of a lineup to an eyewitness sequentially (i.e., one lineup member at a time). For the single-blind, simultaneous condition, administrators knew which lineup member was the suspect and presented the witness with all the lineup members at the same time. Researchers then examined whether witnesses identified the suspect or a known-innocent lineup member at different rates depending on the procedure used. Because the mode of lineup presentation (simultaneous vs. sequential) and the administrator's knowledge of the suspect's identity were confounded, it is impossible to determine whether the increase in suspect identifications found for the single-blind, simultaneous presentations is due to administrator knowledge, the mode of presentation, or some interaction of the two variables. Thus, manipulation of an independent variable protects against confounding only when the manipulation cleanly varies a single construct.

Confounding can also occur in experiments if there is a breakdown in the random assignment of participants to conditions. In applied research, it is not uncommon for partners in the research process to want an intervention delivered to people who deserve or are

in need of the intervention, resulting in the funneling of different types of participants into the treatment and control conditions. Random assignment can also fail if the study's sample size is relatively small because in those situations even random assignment may result in people with particular characteristics appearing in treatment conditions rather than in control conditions merely by chance.

Statistical Methods for Dealing with Confounds

When random assignment to experimental conditions is not possible or is attempted but fails, it is likely that people in the different conditions also differ on other dimensions, such as attitudes, personality traits, and past experience. If it is possible to collect data to measure these confounding variables, then statistical techniques can be used to adjust for their effects on the causal relationship between the independent and dependent variables. One method for estimating the effects of the confounding variables is the calculation of *propensity scores*. A propensity score is the probability of receiving a particular experimental treatment condition given the participants' observed score on a set of confounding variables. Controlling for this propensity score provides an estimate of the true treatment effect adjusted for the confounding variables. The propensity score technique cannot control for the effects of unmeasured confounding variables. Given that it is usually easy to argue for additional confounds in the absence of clean manipulations of the independent variable and random assignment, careful experimental design that rules out alternative explanations for the effects of the independent variable is the best method for eliminating problems associated with confounding.

CONGRUENCE

The congruence between two configurations of points quantifies their similarity. The configurations to be compared are, in general, produced by factor analytic methods (e.g., principal component analysis, correspondence analysis) that decompose an “observations by variables” data matrix and produce one set of factor scores for the observations and one set of factor scores (often called the *loadings*) for the variables. The congruence between two sets of factor scores collected on the same units (which can be observations or variables) measures the similarity between these two sets of scores. If, for example, two different types of factor analysis are performed on the same data set, the congruence between the two solutions is evaluated by the similarity of the configurations of the factor scores produced by these two techniques.

This entry presents three coefficients used to evaluate congruence. The first coefficient is called the *coefficient of congruence*: It measures the similarity of two configurations by computing a cosine between matrices of factor scores. The second and third coefficients are the R_V coefficient and the *Mantel coefficient*. These two coefficients evaluate the similarity of the whole configuration of units. To do so, the factor scores of the units are first transformed into a units-by-units square matrix, which reflects the configuration of similarity between the units and then the similarity between the configurations is measured by a coefficient. For the R_V coefficient, the configuration between the units is obtained by computing a matrix of scalar products between the units, and a cosine between two scalar product matrices evaluates the similarity between two configurations. For the Mantel coefficient, the configuration between the units is obtained by computing a matrix of distance between the units, and a coefficient of correlation between two distance matrices evaluates the similarity between the two configurations described by the distance matrices.

The congruence coefficient was first defined by Cyril Burt—under the name of *unadjusted correlation*—as a measure of the similarity between two factorial configurations. The name *congruence coefficient* was later tailored by Ledyard Tucker. The congruence coefficient is also sometimes called a *monotonicity coefficient*.

The R_V coefficient was introduced by Yves Escoufier as a measure of similarity between squared

symmetric matrices (specifically positive semidefinite matrices) and as a theoretical tool to analyze multivariate techniques. The R_V coefficient is used in several statistical techniques such as STATIS and DISTATIS. To compare rectangular matrices with the R_V or the Mantel coefficients, the first step is to transform these rectangular matrices into square matrices.

The Mantel coefficient was originally introduced by Nathan Mantel in epidemiology, but it is now widely used in ecology.

The congruence and the Mantel coefficients are cosines (the coefficient of correlation is a centered cosine), and as such, they take values between -1 and $+1$. The R_V coefficient is also a cosine, but because it is a cosine between two matrices of scalar products (which, technically speaking, are positive semidefinite matrices), it corresponds actually to a squared cosine, and therefore the R_V coefficient takes values between 0 and 1 .

The computational formulas of these three coefficients are almost identical, but their usage and theoretical foundations differ because these coefficients are applied to different types of matrices. Also, their sampling distributions differ because of the types of matrices on which they are applied.

Notations and Computational Formulas

A vector is an ordered list of numbers, it is denoted by a lower bold letter (e.g., $\mathbf{x}$), its elements are denoted by the same letter typeset in italic with a subscript indicating the order of the element (e.g., x_1 or x_i). By default, vectors are written as columns of numbers: So, for example, the vector $\mathbf{x}$ with three elements can be written as:

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}.$$

The transpose operation transforms a column vector into a row vector, it is denoted by the superscript T , so the previous column vector $\mathbf{x}$, when transposed, becomes a row vector denoted $\mathbf{x}^T = [x_1, x_2, x_3]$. Geometrically, vectors can be interpreted as points in a multidimensional space (with the dimension of the space being equal to the number of elements of the vector). In this framework, the cosine between two vectors, denoted, $\mathbf{x}$ and $\mathbf{y}$, each with I elements is defined as:

$$\cos(\mathbf{x}, \mathbf{y}) = \frac{\sum_i x_i \times y_i}{\sqrt{\left(\sum_i x_i^2\right) \times \left(\sum_i y_i^2\right)}}.$$

Matrices are array of numbers whose dimensions correspond to their number of rows and columns. Matrices are denoted by bold uppercase letters and their elements are denoted by italic lowercase letters with subscript indicating their row and column. So, for example, $\mathbf{X}$ can denote an I rows by J column matrix whose generic element is denoted $x_{i,j}$. The *vec* operation transforms a matrix into a column vector whose entries are the elements of the matrix (i.e., it unfolds the matrix). The cosine between two matrices is defined as the vector cosine between the *vectorized* version of these two matrices. The *trace* operation applies to square matrices and gives the sum of the diagonal elements of this matrix. The transpose operation of a matrix is denoted by the superscript T , it exchanges the roles of the rows and the columns of a matrix, for example, if $\mathbf{X}$ is an I by J , $\mathbf{X}^T$ is a J by I matrix. When two matrices are written next to each other, this indicates matrix multiplication.

Congruence Coefficient

The congruence coefficient is defined when both matrices have the same number of rows and columns (i.e., $J = K$). These matrices can store factor scores (for observations) or factor loadings (for variables). The congruence coefficient is denoted ϕ or sometimes r_c , and it can be computed with three different equivalent formulas:

$$\phi = r_c = \frac{\sum_{i,j} x_{i,j} y_{i,j}}{\sqrt{\left(\sum_{i,j} x_{i,j}^2\right) \left(\sum_{i,j} y_{i,j}^2\right)}}, \quad (1)$$

$$= \frac{\text{vec}\{\mathbf{X}\}^T \text{vec}\{\mathbf{Y}\}}{\sqrt{(\text{vec}\{\mathbf{X}\}^T \text{vec}\{\mathbf{X}\}) (\text{vec}\{\mathbf{Y}\}^T \text{vec}\{\mathbf{Y}\})}}, \quad (2)$$

$$= \frac{\text{trace}\{\mathbf{X}\mathbf{Y}^T\}}{\sqrt{(\text{trace}\{\mathbf{X}\mathbf{X}^T\}) (\text{trace}\{\mathbf{Y}\mathbf{Y}^T\})}}. \quad (3)$$

R_V Coefficient

The R_V coefficient was defined by Robert Escoufier as a similarity coefficient between positive semidefinite matrices (e.g., matrices such as correlation, covariance, or cross-product matrices). Pierre Robert and Robert Escoufier later pointed out that the R_V coefficient had important mathematical properties because most multivariate analysis techniques amount to maximizing—with suitable constraints—this coefficient. Recall, at this point, that a matrix $\mathbf{S}$ is called *positive semidefinite* when it can be obtained as the product of a matrix by

its transpose. Formally, we say that S is positive semidefinite when there exists a matrix X such that

$$S = XX^T. \quad (4)$$

Note that as a consequence of the definition, positive semidefinite matrices are square and symmetric and that their diagonal elements are always larger than or equal to zero.

If S and T denote two positive semidefinite matrices of same dimensions, the R_V coefficient between them is defined as:

$$R_V = \frac{\text{trace}\{S^T T\}}{\sqrt{(\text{trace}\{S^T S\}) \times (\text{trace}\{T^T T\})}}. \quad (5)$$

This formula is computationally equivalent to

$$R_V = \frac{\text{vec}\{S\}^T \text{vec}\{T\}}{\sqrt{(\text{vec}\{S\}^T \text{vec}\{S\}) (\text{vec}\{T\}^T \text{vec}\{T\})}}, \quad (6)$$

$$= \frac{\sum_i \sum_j s_{i,j} t_{i,j}}{\sqrt{\left(\sum_i \sum_j s_{i,j}^2 \right) \left(\sum_i \sum_j t_{i,j}^2 \right)}}. \quad (7)$$

For rectangular matrices, the first step is to transform the matrices into positive semidefinite matrices by multiplying each matrix by its transpose. So in order to compute the value of the R_V coefficient between the I by J matrix X and the I by K matrix Y , the first step is to compute the cross-product matrices S and T :

$$S = XX^T \text{ and } T = YY^T. \quad (8)$$

If we combine Equations 5 and 8, we find that the R_V coefficient between the two rectangular matrices X and Y is equal to

$$R_V = \frac{\text{trace}\{XX^T YY^T\}}{\sqrt{\text{trace}\{XX^T XX^T\} \times \text{trace}\{YY^T YY^T\}}}. \quad (9)$$

The comparison of Equations 3 and 9 shows that the congruence and the R_V coefficients are equivalent only in the case of positive semidefinite matrices.

From a linear algebra point of view, the numerator of the R_V coefficient corresponds to a scalar product between positive semidefinite matrices and therefore gives to this set of matrices the structure of a vector space. Within this framework, the denominator of the R_V coefficient is called the *Frobenius* or *Schur* or *Hilbert-Schmidt* matrix scalar product, and the R_V coefficient is a cosine between matrices. This vector space structure is responsible for the mathematical properties of the R_V coefficient.

Mantel Coefficient

For the Mantel coefficient, if the data are not already in the form of distances, then the first step is to transform these data into distances. These distances can be Euclidean distances, but any other type of distance will work. If D and B denote the two I by I distance matrices of interest (with respective generic elements $d_{i,j}$ and $b_{i,j}$), then the Mantel coefficient between these two matrices is denoted r_M , and it is computed as the coefficient of correlation between their off-diagonal elements as:

$$r_M = \frac{\sum_{i=1}^{I-1} \sum_{j=i+1}^I (d_{i,j} - \bar{d})(b_{i,j} - \bar{b})}{\sqrt{\left[\sum_{i=1}^{I-1} \sum_{j=i+1}^I (d_{i,j} - \bar{d})^2 \right] \left[\sum_{i=1}^{I-1} \sum_{j=i+1}^I (b_{i,j} - \bar{b})^2 \right]}} \quad (10)$$

(where $\bar{d}$ and $\bar{b}$ are the mean of the off-diagonal elements of, respectively, matrices D and B).

Tests and Sampling Distributions

The congruence, the R_V , and the Mantel coefficients all quantify the similarity between two matrices. An obvious practical problem is to be able to perform statistical testing on the value of a given coefficient. In particular, it is often important to be able to decide whether a value of coefficient could have been obtained by chance alone. To perform such statistical tests, one needs to derive the sampling distribution of these coefficients under the null hypothesis (i.e., in order to test whether the population coefficient is null). More sophisticated testing requires one to derive the sampling distribution for different values of the population parameters. So far, analytical methods have failed to completely characterize such distributions, but computational approaches have been used with some success. Because the congruence, the R_V and the Mantel coefficients are used with different types of matrices, their sampling distributions differ, and so work done with each type of coefficient has been carried out independently of the others.

Some approximations for the sampling distributions have been derived recently for the congruence coefficient and the R_V coefficient, with particular attention given to the R_V coefficient. The sampling distribution for the Mantel coefficient has not been satisfactorily approximated, and the statistical tests provided for this coefficient rely mostly on permutation tests.

Congruence Coefficient

Recognizing that analytical methods were unsuccessful, Bruce Korth and Ledyard Tucker decided to use

Monte Carlo simulations to gain some insights into the sampling distribution of the congruence coefficient. Their work was completed by Wendy Broadbooks and Patricia Elmore. From this work, it seems that the sampling distribution of the congruence coefficient depends on several parameters, including the original factorial structure and the intensity of the population coefficient, and therefore no simple picture emerges, but some approximations can be used. In particular, for testing that a congruence coefficient is null in the population, an approximate conservative test is to use Fisher's Z transform and to treat the congruence coefficient like a coefficient of correlation. Broadbooks and Elmore have provided tables for population values different from zero. With the availability of fast computers, these tables can easily be extended to accommodate specific cases.

Example

Here, we use an example from Abdi and Valentin (2007). Two wine experts are rating six wines on three different scales. The results of their ratings are provided in the two matrices below, denoted $\mathbf{X}$ and $\mathbf{Y}$:

$$\mathbf{X} = \begin{bmatrix} 1 & 6 & 7 \\ 5 & 3 & 2 \\ 6 & 1 & 1 \\ 7 & 1 & 2 \\ 2 & 5 & 4 \\ 3 & 4 & 4 \end{bmatrix} \quad \text{and} \quad \mathbf{Y} = \begin{bmatrix} 3 & 6 & 7 \\ 4 & 4 & 3 \\ 7 & 1 & 1 \\ 2 & 2 & 2 \\ 2 & 6 & 6 \\ 1 & 7 & 5 \end{bmatrix}. \quad (11)$$

For computing the congruence coefficient, these two matrices are transformed into two vectors of 6 (products) $\times$ 3 (variables) = 18 elements each, and a cosine (cf. Equation 1) is computed between these two vectors. This gives a value of the coefficient of congruence of $\phi = .7381$. To evaluate whether this value is significantly different from zero, a permutation test with 10,000 permutations was performed. In this test, the rows of one of the matrices were randomly permuted, and the coefficient of congruence was computed for each of these 10,000 permutations. The probability of obtaining a value of $\phi = .7381$ under the null hypothesis was evaluated as the proportion of the congruence coefficients larger than $\phi = .7381$. This gave a value of $p = .0259$, which is small enough to reject the null hypothesis at the .05 α level, and thus one can conclude that the agreement between the ratings of these two experts cannot be attributed to chance.

R_V Coefficient

Statistical approaches for the R_V coefficient have focused on permutation tests. In this framework, the

permutations are performed on the entries of each column of the rectangular matrices $\mathbf{X}$ and $\mathbf{Y}$ used to create the matrices $\mathbf{S}$ and $\mathbf{T}$ or directly on the rows and columns of $\mathbf{S}$ and $\mathbf{T}$. Interestingly Frédérique Kazi-Aoual and colleagues have shown that the mean and the variance of the permutation test distribution can be approximated directly from $\mathbf{S}$ and $\mathbf{T}$. To do so, the first step is to derive an index of the dimensionality or rank of the matrices. This index, denoted β_s (for matrix $\mathbf{S} = \mathbf{X}\mathbf{X}^T$), is also known as ν in the brain imaging literature, where it is called a *sphericity* index and is used as an estimation of the number of degrees of freedom for multivariate tests of the general linear model. The index β_s depends on the set of the L eigenvalues of the $\mathbf{S}$ matrix (i.e., $\mathbf{S}$ has rank L), denoted λ_ℓ , and it is defined as:

$$\beta_s = \frac{\left(\sum_{\ell}^L \lambda_\ell \right)^2}{\sum_{\ell}^L \lambda_\ell^2} = \frac{\text{trace}\{\mathbf{S}\}^2}{\text{trace}\{\mathbf{S}\mathbf{S}\}}. \quad (12)$$

The mean of the set of permuted coefficients between matrices $\mathbf{S}$ and $\mathbf{T}$ is then equal to

$$E(R_V) = \frac{\sqrt{\beta_s \beta_T}}{I-1}. \quad (13)$$

The case of the variance is more complex and involves computing three preliminary quantities for each matrix. The first quantity denoted δ_s is (for matrix $\mathbf{S}$) equal to

$$\delta_s = \frac{\sum_{i,i}^I s_{i,i}^2}{\sum_{\ell}^L \lambda_\ell^2}. \quad (14)$$

The second one is denoted α_s for matrix $\mathbf{S}$ and is defined as:

$$\alpha_s = I - 1 - \beta_s. \quad (15)$$

The third one is denoted C_s (for matrix $\mathbf{S}$) and is defined as:

$$C_s = \frac{(I-1)[I(I+1)\delta_s - (I-1)(\beta_s + 2)]}{\alpha_s(I-3)}. \quad (16)$$

With these notations, the variance of the permuted coefficients is obtained as:

$$V(R_V) = \alpha_s \alpha_T \times \frac{2I(I-1) + (I-3)C_s C_T}{I(I+1)(I-2)(I-1)^3}. \quad (17)$$

For very large matrices, the sampling distribution of the permuted coefficients is relatively similar to a

normal distribution (even though it is, in general, *not* normal), and therefore one can use a Z criterion to perform null hypothesis testing or to compute confidence intervals. For example, the criterion

$$Z_{R_V} = \frac{R_V - E(R_V)}{\sqrt{V(R_V)}} \quad (18)$$

can be used to test the null hypothesis that the observed value of R_V was due to chance.

The problem of the lack of normality of the permutation-based sampling distribution of the R_V coefficient has been addressed by Moonseong Heo and Ruben Gabriel who have suggested *normalizing* the sampling distribution by using a log transformation. Recently Julie Josse, Jerome Pagès, and François Husson have refined this approach and indicated that a gamma distribution would give an even better approximation.

Example

As an example, of the computation of the R_V we use the two scalar product matrices obtained from the matrices used to illustrate the congruence coefficient (cf. Equation 11). For the present example, these original matrices are centered (i.e., the mean of each column has been subtracted from each element of the column) prior to computing the scalar product matrices. Specifically, if $\bar{X}$ and $\bar{Y}$ denote the centered matrices derived from X and Y , we obtain the following scalar product matrices:

$$S = \bar{X}\bar{X}^T = \quad (19)$$

$$\begin{bmatrix} 29.56 & -8.78 & -20.78 & -20.11 & 12.89 & 7.22 \\ -8.78 & 2.89 & 5.89 & 5.56 & -3.44 & -2.11 \\ -20.78 & 5.89 & 14.89 & 14.56 & -9.44 & -5.11 \\ -20.11 & 5.56 & 14.56 & 16.22 & -10.78 & -5.44 \\ 12.89 & -3.44 & -9.44 & -10.78 & 7.22 & 3.56 \\ 7.22 & -2.11 & -5.11 & -5.44 & 3.56 & 1.89 \end{bmatrix}$$

and

$$T = \bar{Y}\bar{Y}^T = \quad (20)$$

$$\begin{bmatrix} 11.81 & -3.69 & -15.69 & -9.69 & 8.67 & 7.81 \\ -3.69 & 1.81 & 7.31 & 1.81 & -3.53 & -3.69 \\ -15.19 & 7.31 & 34.81 & 9.31 & -16.03 & -20.19 \\ -9.69 & 1.81 & 9.31 & 10.81 & -6.53 & -5.69 \\ 8.97 & -3.53 & -16.03 & -6.53 & 8.14 & 8.97 \\ 7.81 & -3.69 & -20.19 & -5.69 & 8.97 & 12.81 \end{bmatrix}$$

We find the following value for the R_V coefficient:

$$R_V = \frac{\sum_i \sum_j s_{i,j} t_{i,j}}{\sqrt{\left(\sum_i \sum_j s_{i,j}^2 \right) \left(\sum_i \sum_j t_{i,j}^2 \right)}} \quad (21)$$

$$= \frac{(29.56 \times 11.81) + (-8.78 \times -3.69) + \dots + (1.89 \times 12.81)}{\sqrt{[(29.56)^2 + (-8.78)^2 + \dots + (1.89)^2][(11.81)^2 + (-3.69)^2 + \dots + (12.81)^2]}}$$

$$= .7936.$$

To test the significance of a value of $R_V = .7936$ we first compute the following quantities:

$$\begin{aligned} \beta_s &= 1.0954 & \alpha_s &= 3.9046 \\ \delta_s &= 0.2951 & C_s &= -1.3162 \\ \beta_T &= 1.3851 & \alpha_T &= 3.6149 \\ \delta_T &= 0.3666 & C_T &= -0.7045. \end{aligned} \quad (22)$$

Plugging these values into Equations 13, 17, and 18, we find

$$\begin{aligned} E(R_V) &= 0.2464, \\ V(R_V) &= 0.0422, \text{ and} \\ Z_{R_V} &= 2.66. \end{aligned} \quad (23)$$

Assuming a normal distribution for the Z_{R_V} gives a p value of .0077, which would allow for the rejection of the null hypothesis for the observed value of the R_V coefficient.

Permutation Test

As an alternative approach to evaluate whether the value of $R_V = .7936$ is significantly different from zero, a permutation test with 10,000 permutations was performed. In this test, the whole set of rows *and* columns (i.e., the *same* permutation of I elements is used to permute rows and columns) of one of the scalar product matrices was randomly permuted, and the R_V coefficient was computed for each of these 10,000 permutations. The probability of obtaining a value of $R_V = .7936$ under the null hypothesis was evaluated as the proportion of the R_V coefficients larger than $R_V = .7936$. This gave a value of $p = .0281$, which is small enough to reject the null hypothesis at the .05 α level. It is worth noting that the normal approximation gives a more liberal (i.e., smaller) value of p than does the nonparametric permutation test (which is more accurate in this case because the sampling distribution of R_V is not normal).

Mantel Coefficient

The exact sampling distribution of the Mantel coefficient is not known. Numerical simulations suggest

that when the distance matrices originate from different independent populations, the sampling distribution of the Mantel coefficient is symmetric (though not normal) with a zero mean. In fact, Mantel, in his original paper, presented some approximations for the variance of the sampling distributions of r_M (derived from the permutation test) and suggested that a normal approximation could be used, but the problem is still open. In practice, however, the probability associated to a specific value of r_M is derived from permutation tests.

Example

As an example, two distance matrices derived from the congruence coefficient example (cf. Equation 11) are used. These distance matrices can be computed directly from the scalar product matrices used to illustrate the computation of the R_V coefficient (cf. Equations 19 and 20). Specifically, if S is a scalar product matrix and if s denotes the vector containing the diagonal elements of S , and if $\mathbf{1}$ denotes an I by 1 vector of ones, then the matrix D of the squared Euclidean distances between the elements of S is obtained as (cf. Equation 4):

$$D = \mathbf{1}s^T + s\mathbf{1}^T - 2S. \quad (24)$$

Using Equation 24, we transform the scalar-product matrices from Equations 19 and 20 into the following distance matrices:

$$D = \begin{bmatrix} 0 & 50 & 86 & 86 & 11 & 17 \\ 50 & 0 & 6 & 8 & 17 & 9 \\ 86 & 6 & 0 & 2 & 41 & 27 \\ 86 & 8 & 2 & 0 & 45 & 29 \\ 11 & 17 & 41 & 45 & 0 & 2 \\ 17 & 9 & 27 & 29 & 2 & 0 \end{bmatrix} \quad (25)$$

and

$$T = \begin{bmatrix} 0 & 21 & 77 & 42 & 2 & 9 \\ 21 & 0 & 22 & 9 & 17 & 22 \\ 77 & 22 & 0 & 27 & 75 & 88 \\ 42 & 9 & 27 & 0 & 32 & 35 \\ 2 & 17 & 75 & 32 & 0 & 3 \\ 9 & 22 & 88 & 35 & 3 & 0 \end{bmatrix}. \quad (26)$$

For computing the Mantel coefficient, the upper diagonal elements of each of these two matrices are stored into a vector of $\frac{1}{2}I \times (I - 1) = 15$ elements, and the standard coefficient of correlation is computed between these two vectors. This gives a value of the Mantel coefficient of $r_M = .5769$. To evaluate whether

this value is significantly different from zero, a permutation test with 10,000 permutations was performed. In this test, the whole set of rows *and* columns (i.e., the *same* permutation of I elements is used to permute rows and columns) of one of the matrices was randomly permuted, and the Mantel coefficient was computed for each of these 10,000 permutations. The probability of obtaining a value of $r_M = .5769$ under the null hypothesis was evaluated as the proportion of the Mantel coefficients larger than $r_M = .5769$. This gave a value of $p = .0265$, which is small enough to reject the null hypothesis at the .05 α level.

Conclusion

The congruence, R_V , and Mantel coefficients all measure slightly different aspects of the notion of congruence. The congruence coefficient is sensitive to the pattern of similarity of the columns of the matrices and therefore will not detect similar configurations when one of the configurations is rotated or dilated. By contrast, both the R_V coefficient and the Mantel coefficients are sensitive to the whole configuration and are insensitive to changes in configuration that involve rotation or dilatation. The R_V coefficient has the additional merit of being theoretically linked to most multivariate methods and of being the base of Procrustes methods such as STATIS or DISTATIS.

CONNECTIVITY

Connectivity as a research design term has its origins in mathematical graph theory referring to whether the vertices (nodes or people) of a graph are reachable to one another through direct and indirect ties. The transition of the meaning of connectivity from purely mathematical description to relationships defined mathematically

has been most manifest in the field of social network analysis. Although social network analysis originated in the empirical observations of bees, the field now almost exclusively focuses on the relations between humans as influenced by their positionality within institutions as well as those that they interact and are in contact with in other everyday life situations.

The social network view of human connectivity is grounded in third-person perspectives, which is often captured by surveys with questions asking who people turn to or rely on for various instrumental actions (e.g., advice seeking in an organization, staying updated on the newest trends). In contrast to an observational stance by which researchers observe the actions of others (or bees), a first-person perspective of connectivity is best captured by phenomenological or experiential terms, such as intersubjectivity. From this perspective, connectivity refers to the perceived or ethereal experiences of belonging or how one *experiences* being situated in a community or society, which are often related to concepts such as regard and/or recognition. Thus, connectivity spans a spectrum of meanings from manifest to latent, from articulated to unconscious or embodied experiences. Currently, the term is used to include both mathematical and humanistic approaches.

The number of terms that could be accounted for by the concept of “connectivity” is as varied and broad as the number of theories focused on the linkages, relationships, and ties between entities. Which research design a researcher utilizes will depend primarily on the research questions asked and the paradigm by which connectivity is viewed. These will guide choice in epistemology and, thus, methodology. A positivist paradigm, for example, would focus attention on *explaining* connectivity and an interpretive paradigm toward *understanding* the experiences of connectivity. A critical paradigm might focus on connectivity in terms of *power*, while a transformative paradigm might ask how connectivity could *change* knowledge, attitudes, and/or practices. Primary terms of connectivity used in research—networks, intersubjectivity, positionality, and diffusion—could be representative of these different paradigms. These four concepts are by no means all-encompassing nor representative of all forms of connectivity but are particularly well-suited to illustrate how the research question and research paradigm chosen will influence results. To illustrate this, the remainder of this entry provides examples linking “connectivity” using three of the four different paradigms.

Positivist, Postpositivist Paradigm

To *explain* connectivity, social network analysis measures at the individual and/or network level can be used

to describe the structure and function of social relationships. For example, a researcher can measure who are friends with whom in a school (e.g., “Who are your closest friends?”) to explain how friendship influences an array of health-related social behaviors, such as tobacco use, suicide, and/or violence. An individual measure would account for the number of friends that a person identifies as well as whether those friendships are reciprocated. A network-level measure would be the volume of friendships in the school and whether the overall pattern is a function of individual characteristics (e.g., sex, ethnicity).

Interpretive Paradigm

To *understand* connectivity, a variety of methods which provide a first-person account and details about *experiences* of connectivity can be used. These can be collected by participant observations in which the observer also participates in a shared event or activity with the interlocutor, through individual or group interviews using questions designed to elicit significant or memorable experiences around connectivity (e.g., What stood out for you when you felt connected to . . . ? Can you give an example of when you felt connected to . . . ?). Such questions are easily applicable to questions designed to understand the relationship between connectivity and friendship and/or connectivity, friendship, and experiences of well-being that also lead to theoretical developments, such as how persons are “socially occupied beings” who do “things that matter with others” (Lawlor, 2003, p. 432).

Transformative Paradigm

The transformative paradigm is a relatively recent one. Using research to *create change* in connectivity relies on participatory approaches to engage stakeholders or end users of the research in the research process itself, to varying degrees. Participants become coresearchers in identifying priority concerns, collecting data, analyzing data, and cocreating actions to redress their concerns. Here, the methodological measures are like those in the other paradigms, but the emphasis shifts from description or explanation and understanding to purposive attempts to change conditions. If, for example, participants as coresearchers identify a lack of resources as a priority concern, the researcher could use social network analysis to identify key stakeholders (e.g., opinion leaders, bridges) who can provide those resources and/or can help the researcher understand the barriers and/or supports in the local context. In this way, network data can be used to make recommendations, even prescriptions, for how to engage change at

the social level. For example, school-based friendships can be used to identify popular opinion leaders who can promote prosocial behaviors to their peers and/or help them understand or reenvision how “connectivity” can address larger concerns. Alternatively, first-person perspectives could be used to create third-person representations of change by which persons can envision the impact on and of social networks over time.

Final Thoughts

Considering connectivity through these three research paradigms illuminates its primary contributions to research. First, the synergistic effects of connectivity are located between structural measures and/or third-person perspectives of connectivity and what might really matter to individuals on the ground from an intimate, experiential level (first-person perspectives). Second, using methods from social network analysis, grounded in positivist approaches, to understand behavior and close attention in interpretive approaches to the *meaning* of situated engagement activities or events of particular persons is necessary to explain and understand transformation. Finally, participatory approaches to network interventions can instigate and support the sustainability of transformative actions and their effects.

CONSTRUCT VALIDITY

Construct validity refers to whether the scores of a test or instrument measure the distinct dimension (construct) they are intended to measure. The present entry discusses origins and definitions of construct

validation, methods of construct validation, the role of construct validity evidence in the validity argument, and unresolved issues in construct validity.

Origins and Definitions

Construct validation generally refers to the collection and application of validity evidence intended to support the interpretation and use of test scores as measures of a particular construct. The term *construct* denotes a distinct dimension of individual variation, but the use of this term typically carries the connotation that the construct does not allow for direct observation but rather depends on indirect means of measurement. As such, the term *construct* differs from the term *variable* with respect to this connotation. Moreover, the term *construct* is sometimes distinguished from the term *latent variable* because construct connotes a substantive interpretation typically embedded in a body of substantive theory. In contrast, the term *latent variable* refers to a dimension of variability included in a statistical model with or without a clear substantive or theoretical understanding of that dimension and thus can be used in a purely statistical sense. For example, the *latent traits* in item response theory analysis are often introduced as latent variables but not associated with a particular construct until validity evidence supports such an association.

The object of validation has evolved with validity theory. Initially, validation was construed in terms of the validity of a test. Lee Cronbach and others pointed out that validity depends on how a test is scored. For example, detailed content coding of essays might yield highly valid scores, whereas general subjective judgments might not. As a result, validity theory shifted its focus from validating tests to validating test scores. In addition, it became clear that the same test scores could be used in more than one way and that the level of validity could vary across uses. For example, the same test scores might offer a highly valid measure of intelligence but only a moderately valid indicator of attention deficit hyperactivity disorder. As a result, the emphasis of validity theory again shifted from test scores to test score interpretations. Yet a valid interpretation often falls short of justifying a particular use. For example, an employment test might validly measure propensity for job success, but another available test might do as good a job at the same cost but with less adverse impact. In such an instance, the validity of the test score interpretation for the first test would not justify its use for employment testing. Thus, Samuel Messick has urged that test scores are rarely interpreted in a vacuum as a purely academic exercise but are rather collected for some purpose and put to some use.

However, in common parlance, one frequently expands the notion of test to refer to the entire procedure of collecting test data (testing), assigning numeric values based on the test data (scoring), making inferences about the level of a construct on the basis of those scores (interpreting), and applying those inferences to practical decisions (use). Thus, the term *test validity* lives on as shorthand for the validity of test score interpretations and uses.

Early on, tests were thought to divide into two types: signs and samples. If a test was interpreted as a sign of something else, the something else was understood as a construct, and construct validation was deemed appropriate. For example, responses to items on a personality inventory might be viewed as signs of personality characteristics, in which case the personality characteristic constitutes the construct of interest. In contrast, some tests were viewed as only samples, and construct validation was not deemed necessary. For example, a typing test might sample someone's typing and assess its speed and accuracy. The scores on this one test (produced from a sampling of items that could appear on a test) were assumed to generalize merely on the basis of statistical generalization from a sample to a population. Jane Loevinger and others questioned this distinction by pointing out that the test sample could never be a random sample of all possible exemplars of the behavior in question. For example, a person with high test anxiety might type differently on a typing test from the way the person types at work, and someone else might type more consistently on a brief test than over a full workday. As a result, interpreting the sampled behavior in terms of the full range of generalization always extends beyond mere statistical sampling to broader validity issues. For this reason, all tests are signs as well as samples, and construct validation applies to all tests.

At one time, test validity was neatly divided into three types—content, criterion, and construct—with the idea that one of these three types of validity applied to any one type of test. However, criterion-related validity depends on the construct interpretation of the criterion, and test fairness often turns on construct-irrelevant variance in the predictor scores. Likewise, content validation may offer valuable evidence in support of the interpretation of correct answers but typically will not provide as strong a line of evidence for the interpretation of incorrect answers. For example, someone might know the mathematical concepts but answer a math word problem incorrectly because of insufficient vocabulary or culturally inappropriate examples. Because all tests involve interpretation of the test scores in terms of what they are intended to measure, construct validation applies to all tests. In

contemporary thinking, there is a suggestion that all validity should be of one type, construct validity.

This line of development has led to unified (but not unitary) conceptions of validity that elevate construct validity from one kind of validity among others to the whole of validity. Criterion-related evidence provides evidence of construct validity by showing that test scores relate to other variables (i.e., criterion variables) in the predicted ways. Content validity evidence provides evidence of construct validity because it shows that the test properly covers the intended domain of content related to the construct definition. As such, construct validity has grown from humble origins as one relatively esoteric form of validity to the whole of validity, and it has come to encompass other forms of validity evidence.

Messick distinguished two threats to construct validity. Construct deficiency applies when a test fails to measure some aspects of the construct that it should measure. For example, a mathematics test that failed to cover some portion of the curriculum for which it was intended would demonstrate this aspect of poor construct validity. In contrast, *construct-irrelevant variance* involves things that the test measures that are not related to the construct of interest and thus should not affect the test scores. The example of a math test that is sensitive to vocabulary level illustrates this aspect. A test with optimal construct validity therefore measures everything that it should measure but nothing that it should not.

Traditionally, validation has been directed toward a specific test, its scores, and their intended interpretation and use. However, construct validation increasingly conceptualizes validation as continuous with extended research programs into the construct measured by the test or tests in question. This shift reflects a broader shift in the behavioral sciences away from *operationalism*, in which a variable is theoretically defined in terms of a single *operational definition*, in favor of *multioperationalism*, in which a variety of different measures triangulate on the same construct. As a field learns to measure a construct in various ways and learns more about how the construct relates to other variables through evidence collected using these measures, the overall understanding of the construct increases. The stronger this overall knowledge base about the construct, the more confidence one can have in interpreting the scores derived from a particular test as measuring this construct. Moreover, the more one knows about the construct, the more specific and varied are the consequences entailed by interpreting test scores as measures of that construct. As a result, one can conceptualize construct validity as broader than test validity because it involves the collection of evidence to validate

theories about the underlying construct as measured by a variety of tests, rather than merely the interpretation of scores from one particular test.

Construct Validation Methodology

At its inception, when construct validity was considered one kind of validity appropriate to certain kinds of tests, inspection of patterns of correlations offered the primary evidence of construct validity. Lee Cronbach and Paul Meehl described a *nomological net* as a pattern of relationships between variables that partly fixed the meaning of a construct. Later, factor analysis established itself as a primary methodology for providing evidence of construct validity. Loevinger described a *structural aspect* of construct validity as the pattern of relationships between items that compose a test. Factor analysis allows the researcher to investigate the internal structure of item responses, and some combination of replication and confirmatory factor analysis allows the researcher to test theoretical hypotheses about that structure. Such hypotheses typically involve multiple dimensions of variation tapped by items on different subscales and therefore measuring different constructs. A higher order factor may reflect a more general construct that comprises these subscale constructs.

Item response theory typically models dichotomous or polytomous item responses in relation to an underlying latent trait. Although item response theory favors the term *trait*, the models apply to all kinds of constructs. Historically, the emphasis with item response theory has been much more heavily on unidimensional measures and providing evidence that items in a set all measure the same dimension of variation. However, recent developments in factor analysis for dichotomous and polytomous items, coupled with expanded interest in multidimensional item response theory, have brought factor analysis and item response theory together under one umbrella. Item response theory models are generally equivalent to a factor analysis model with a threshold at which item responses change from one discrete response to another based on an underlying continuous dimension. Both factor analysis and item response theory depend on a shared assumption of *local independence*, which means that if one held constant the underlying latent variable, the items would no longer have any statistical association between them. Latent class analysis offers a similar measurement model based on the same basic assumption but applicable to situations in which the latent variable is itself categorical. All three methods typically offer tests of goodness of fit based on the assumption of local independence and the ability of the modeled latent variables to account for the relationships among the item responses.

An important aspect of the above types of evidence involves the separate analysis of various scales or subscales. Analyzing each scale separately does not provide evidence as strong as does analyzing them together. This is because separate analyses work only with local independence of items on the same scale. Analyzing multiple scales combines this evidence with evidence based on relationships between items on different scales. So, for example, three subscales might each fit a one-factor model very well, but a three-factor model might fail miserably when applied to all three sets of items together. Under a hypothetico-deductive framework, testing the stronger hypothesis of multiconstruct local independence offers more support to interpretations of sets of items that pass it than does testing a weaker piecemeal set of hypotheses.

The issue just noted provides some interest in returning to the earlier notion of a nomological net as a pattern of relationships among variables in which the construct of interest is embedded. The idea of a nomological net arose during a period when causation was suspect and laws (i.e., nomic relationships) were conceptualized in terms of patterns of association. In recent years, causation has made a comeback in the behavioral sciences, and methods of modeling networks of causal relations have become more popular. Path analysis can be used to test hypotheses about how a variable fits into such a network of observed variables, and thus path analysis provides construct validity evidence for test scores that fit into such a network as predicted by the construct theory. Structural equation models allow the research to combine both ideas by including both *measurement models* relating items to latent variables (as in factor analysis) and *structural models* that embed the latent variables in a causal network (as in path analysis). These models allow researchers to test complex hypotheses and thus provide even stronger forms of construct validity evidence. When applied to passively observed data, however, such causal models contain no magic formula for spinning causation out of correlation. Different models will fit the same data, and the same model will fit data generated by different causal mechanisms. Nonetheless, such models allow researchers to construct highly falsifiable hypotheses from theories about the construct that they seek to measure.

Complementary to the above, experimental and quasi-experimental evidence also plays an important role in assessing construct validity. If a test measures a given construct, then efforts to manipulate the value of the construct should result in changes in test scores. For example, consider a standard program evaluation study that demonstrates a causal effect of a particular training program on performance of the targeted skill

set. If the measure of performance is well validated and the quality of the training is under question, then this study primarily provides evidence in support of the training program. In contrast, however, if the training program is well validated but the performance measure is under question, then the same study primarily provides evidence in support of the construct validity of the measure. Such evidence can generally be strengthened by showing that the intervention affects the variables that it should but also does not affect the variables that it should not. Showing that a test is responsive to manipulation of a variable that should not affect it offers one way of demonstrating construct-irrelevant variance. For example, admissions tests sometimes provide information about test-taking skills in an effort to minimize the responsiveness of scores to further training in test taking.

Susan Embretson distinguished *construct representation* from *nomothetic span*. The latter refers to the external patterns of relationships with other variables and essentially means the same thing as nomological net. The former refers to the cognitive processes involved in answering test items. To the extent that answering test items involves the intended cognitive processes, the construct is properly represented, and the measurements have higher construct validity. As a result, explicitly modeling the cognitive operation involved in answering specific item types has blossomed as a means of evaluating construct validity, at least in areas in which the underlying cognitive mechanisms are well understood. As an example, if one has a strong construct theory regarding the cognitive processing involved, one can manipulate various cognitive subtasks required to answer items and predict the difficulty of the resulting items from these manipulations.

Role in Validity Arguments

Modern validity theory generally structures the evaluation of validity on the basis of various strands of evidence in terms of the construction of a *validity argument*. The basic idea is to combine all available evidence into a single argument supporting the intended interpretation and use of the test scores. Recently, Michael Kane has distinguished an *interpretive argument* from the validity argument. The interpretive argument spells out the assumptions and rationale for the intended interpretation of the scores, and the validity argument supports the validity of the interpretive argument, particularly by providing evidence in support of key assumptions. For example, an interpretive argument might indicate that an educational performance mastery test assumes prior exposure and practice with the material. The validity argument might then provide

evidence that given these assumptions, test scores correspond to the degree of mastery.

The key to developing an appropriate validity argument rests with identifying the most important and controversial premises that require evidential support. Rival hypotheses often guide this process. The two main threats to construct validity described above yield two main types of rival hypotheses addressed by construct validity evidence. For example, sensitivity to transient emotional states might offer a rival hypothesis to the validity of a personality scale related to construct-irrelevant variance. *Differential item functioning*, in which test items relate to the construct differently for different groups of test takers, also relates to construct-irrelevant variance, yielding rival hypotheses about test scores related to group characteristics. A rival hypothesis that a clinical depression inventory captures only one aspect of depressive symptoms involves a rival hypothesis about construct deficiency.

Unresolved Issues

A central controversy in contemporary validity theory involves the disagreements over the breadth of validity evidence. Construct validation provides an integrative framework that ties together all forms of validity evidence in a way continuous with empirical research into the construct, but some have suggested a less expansive view of validity as more practical. Construct validity evidence based on test consequences remains a continuing point of controversy, particularly with respect to the notion of *consequential validity* as a distinct form of validity. Finally, there remains a fundamental tension in modern validity theory between the traditional fact-value dichotomy and the fundamental role of values and evaluation in assessing the evidence in favor of specific tests, scores, interpretations, and uses.

CONTENT ANALYSIS

Content analysis is a research technique for making replicable and valid inferences from texts (or other meaningful matter) to the context of their use. This entry further explores the definition and conceptions of content analysis. It then provides information on its conceptual framework and the steps involved in performing content analysis.

Definition and Conception

The phrase *content analysis*, first mentioned in a 1941 paper by Douglas Waples and Bernard Berelson, became defined in 1948 by Paul F. Lazarsfeld and Berelson. *Webster's Dictionary* has listed *content analysis* since its 1961 edition. However, the practice of analyzing media matter is almost as old as writing. It became of interest to the church, worried about the effects of the written word other than God's; to governments, trying to settle political, legal, and religious disputes; to journalists, hoping to document the changes in newspaper publishing due to its commercialization and popularization; to corporations interested in surveying their symbolic environments for opportunities and threats; and to social scientists, originally drawn into the competition between the press and newly emerging media, then radio and television, but soon discovering the importance of all kinds of mediated communication to understand social, political, economic, and psychological phenomena. Communication research advanced content analysis, but owing to the proliferation of media and the recognition that humans define themselves and each other in communication, coordinate their beliefs and actions in communication, and construct the realities they live with in communication, content analysis is now used by literally all social sciences.

As a technique, content analysis embraces specialized procedures. It is teachable. Its use can be divorced from the authority of the researcher. As a research technique, content analysis can provide new kinds of understanding social phenomena or inform decisions on pertinent actions. Content analysis is a scientific tool.

All techniques are expected to be reliable. Scientific research techniques should result in replicable findings. Replicability requires research procedures to be explicit and communicable so that researchers, working at different times and perhaps under different circumstances, can apply them and come to the same conclusions about the same phenomena.

Scientific research must also yield valid results. To establish validity, research results must survive in the face of independently available evidence of what they claim. The methodological requirements of reliability and validity are not unique to content analysis but make particular demands on the technique that are not found as problematic in other methods of inquiry.

The reference to *text* is not intended to restrict content analysis to written material. The parenthetical phrase *or other meaningful matter* is to imply content analysis's applicability to anything humanly significant: images, works of art, maps, signs, symbols, postage stamps, songs, and music, whether mass produced, created in conversations, or private. Texts, whether composed by individual authors or produced by social institutions, are always intended to point their users to something beyond their physicality. However, content analysis does not presume that readers read a text as intended by its source; in fact, authors may be quite irrelevant, often unknown. In content analysis, available texts are analyzed to answer research questions not necessarily shared by everyone.

What distinguishes content analysis from most observational methods in the social sciences is that *the answers to its research questions are inferred from available text*. Content analysts are not interested in the physicality of texts that can be retrieved, quantified, and objectively measured. The pixels of digital images, the sounds one can manipulate at a control panel, and the alphabetical characters of written matter one can create on a computer screen are mere vehicles of communication. What text means to somebody, what it represents, highlights and excludes, encourages or deters—all these phenomena do not reside inside a text but come to light in processes of someone's reading, interpreting, analyzing, concluding, and in the case of content analysis, answering pertinent research questions concerning the text's context of use.

Typical research questions that content analysts might answer are as follows: What are the consequences for heavy and light viewers of exposure to violent television shows? What are the attitudes of a writer on issues not mentioned? Who is the author of an anonymously written work? Is a suicide note real, requiring intervention, or an empty threat? Which of two textbooks is more readable by sixth graders? What is the likely diagnosis for a psychiatric patient, known

through an interview or the responses to a Rorschach test? What is the ethnic, gender, or ideological bias of a newspaper? Which economic theory underlies the reporting of business news in the national press? What is the likelihood of cross-border hostilities as a function of how one country's national press portrays its neighbor? What are a city's problems as inferred from citizens' letters to its mayor? What do school children learn about their nation's history through textbooks? What criteria do internet users employ to authenticate electronic documents?

Other Conceptions

Unlike content analysis, observation and measurement go directly to the phenomenon of analytic interest. Temperature and population statistics describe tangible phenomena. Experiments with human participants tend to define the range of responses in directly analyzable form, just as structured interviews delineate the interviewees' multiple choices among answers to prepared interview questions. Structured interviews and experiments with participants acknowledge subjects' responses to meanings but bypass their nature by standardization. Content analysts struggle with unstructured meanings.

Social scientific literature does contain conceptions of content analysis that mimic observational methods, such as those of George A. Miller who characterizes content analysis as a method for putting large numbers of units of verbal matter into analyzable categories. A definition of this kind provides no place for methodological standards. Berelson's widely cited definition fares not much better. For him, "content analysis is a research technique for the objective, systematic and quantitative description of the manifest content of communication" (1952, p. 18). The restriction to manifest content would rule out content analyses of psychotherapeutic matter or of diplomatic exchanges, both of which tend to rely on subtle clues to needed inferences. The requirement of quantification, associated with objectivity, has been challenged, especially because the reading of text is qualitative to start, and interpretive research favors qualitative procedures without being unscientific. Taking the questionable attributes out of Berelson's definition reduces content analysis to the systematic analysis of content, which relies on a metaphor of content that locates the object of analysis inside the text—a conception that some researchers believe is not only misleading but also prevents the formulation of sound methodology.

There are definitions, such as Charles Osgood's or Ole Holsti's, that admit inferences but restrict them to the source or destination of the analyzed messages.

These definitions provide for the use of validity criteria by allowing independent evidence to be brought to bear on content analysis results, but they limit the analysis to causal inferences.

Conceptual Framework

Figure 1 depicts the methodologically relevant elements of content analysis. A content analysis usually starts with either or both (a) available text that, on careful reading, poses scientific research questions or (b) research questions that lead the researcher to search for texts that could answer them.

Research Questions

In content analysis, research questions need to go outside the physicality of text into the world of others. The main motivation for using content analysis is that the answers sought cannot be found by direct observation, be it because the phenomena of interest are historical, hence past; enshrined in the mind of important people, not available for interviews; concern policies that are deliberately hidden, as by wartime enemies; or concern the anticipated effects of available communications, hence not yet present. If these phenomena were observable directly, content analysis of texts would be redundant. Content analysts pursue questions that could conceivably be answered by examining texts but that could also be validated by other means, at least in principle.

The latter rules out questions that have to do with a researcher's skill in processing text, albeit

systematically. For example, the question of "how can I measure violence on television" pertains to a researcher's abilities, which have to be taken for granted in content analysis. The question of how much violence is featured on television is answerable by counting incidences of it. For content analysts, an index of violence on television needs to have empirical validity in the sense that it needs to say something about how audiences of violent shows react, how their conception of the world is shaped by being exposed to television violence, or whether it encourages or discourages engaging in violent acts. Inferences about antecedents and consequences can be validated, at least in principle. Counts can be validated only by recounting. Without designating where validating evidence could be found, statements about the physicality of text would not answer the research questions that define a content analysis.

Research questions must admit alternative answers among which data decide. They are similar to a set of hypotheses to be tested, except that inferences from text determine choices among them.

Context of the Analysis

All texts can be read in multiple ways and provide diverging information to readers with diverging competencies and interests. Content analysts are not different in this regard, except for their mastery of analytical techniques. To keep the range of possible inferences manageable, content analysts need to construct a context in which their research questions can be related to available texts in ways that are transparent and

Figure 1 A Framework for Content Analysis

available for examination by fellow scientists. This restriction is quite natural. Psychologists construct their world unlike sociologists do, and what is relevant when policy recommendation or evidence in court needs to be provided may have little to do with an analysis that aims at deciding when different parts of the Bible were written. The context of a content analysis always is the analyst's choice. There are no restrictions except for having to be explicit and arguably related to the world of others for whom the analyzed text means something, refers to something, and is useful or effective, although not necessarily as content analysts conceptualize these things.

Description of Text

Usually, the first step in a content analysis is a description of the text. Mary Bock called content analyses that stop there *impressionistic* because they leave open what a description could mean. Three types of description may be distinguished: (1) selected word counts, (2) categorizations by common dictionaries or thesauri, and (3) interpretations and recording or scaling by human coders.

Selected Word Counts

Selected word counts can easily be obtained mechanically and afford numerous comparisons by sources or situations or over time. For example, the 12 most frequent words uttered by Paris Hilton in an interview with Larry King were 285 *I*, 66 *you*, 61 *my*, 48 *like*, 45 *yes*, 44 *really*, 40 *me*, 33 *I'm*, 32 *people*, 28 *they*, 17 *life* and *time*, and 16 *jail*. That *I* is by far the most frequent word may suggest that the interviewee talked largely about herself and her own life, which incidentally included a brief visit in jail. Such a distribution of words is interesting not only because normally one does not think about words when listening to conversations but also because its skewedness is quite unusual and invites explanations. But whether Hilton is self-centered, whether her response was due to King's questioning, how this interview differed from others he conducted, and what the interview actually revealed to the television audience remain speculation. Nevertheless, frequencies offer an alternative to merely listening or observing.

Many computer aids to content analysis start with words, usually omitting function words, such as articles, stemming them by removing grammatical endings, or focusing on words of particular interest. In that process, the textual environments of words are abandoned or, in the case of *keywords in context* lists, significantly reduced.

Categorizing by Common Dictionaries or Thesauri

Categorization by common dictionaries or thesauri is based on the assumptions that (a) textual meanings reside in words, not in syntax and organization; (b) meanings are shared by everyone—*manifest*, in Berelson's definition—as implied in the use of published dictionaries and thesauri; and (c) certain differentiations among word meanings can be omitted in favor of the gist of semantic word classes. Tagging texts is standard in several computer aids for content analysis. The General Inquirer software, for example, assigns the words *I*, *me*, *mine*, and *myself* to the tag "self" and the tags "self," "selves," and "others" to the second-order tag "person." Where words are ambiguous, such as *play*, the General Inquirer looks for disambiguating words in the ambiguous word's environment—looking, in the case of *play*, for example, for words relating to children and toys, musical instruments, theatrical performances, or work—and thereby achieves a less ambiguous tagging. Tagging is used to scale favorable or unfavorable attributes, as in sentiment analyses, or to distinguish genuine *versus* fictional accounts of events.

Interpreting, Recording, or Scaling by Human Coders

Interpreting and recording or scaling by human coders is the traditional and by far the most common path taken to obtain analyzable descriptions of text. The demand for content analysis to be reliable is met by standard coding instructions, which all coders are asked to apply uniformly to the same set of phenomena, the units of analysis. Units may be words, propositions, paragraphs, news items, or whole publications of printed matter; scenes, actors, episodes, or whole movies in the visual domain; or utterances, turns taken, themes discussed, or decisions made in conversations.

The use of standard coding instructions offers content analysts not only the possibility of analyzing larger volumes of text and employing many coders but also a choice between *emic* and *etic* descriptions—*emic* by relying on the very categories that a designated group of readers would use to describe the textual matter, *etic* by deriving coding categories from the theories of the context that the content analysts have adopted. The latter choice enables content analysts to describe latent contents and approach phenomena that ordinary writers and readers may not be aware of. *Good* and *bad* are categories nearly everyone understands alike, but *pro-social* and *antisocial* attitudes, the concept of framing, or the idea of a numerical strength of word associations need to be carefully defined, exemplified, and tested for reliability.

Inference

Abduction

Although sampling considerations are important in selecting texts for analysis, the type of inference that distinguishes content analysis from observational methods is abduction—not induction or deduction. Abduction proceeds from particulars—texts—to essentially different particulars—the answers to research questions. For example, inferring the identity of the author from textual qualities of an unsigned work inferring levels of anxiety from speech disturbances inferring a source's conceptualization from the proximity of words it uses inferring Joseph Stalin's successor from public speeches by Politburo members at the occasion of Stalin's birthday or inferring possible solutions to a conflict entailed by the metaphors used in characterizing that conflict.

Analytical Constructs

Inferences of this kind require some evidential support that should stem from the known, assumed, theorized, or experimentally confirmed stable correlations between the textuality as described and the set of answers to the research question under investigation. Usually, this evidential support needs to be operationalized into a form applicable to the descriptions of available texts and interpretable as answers to the research questions. Such operationalizations can take numerous forms. By intuition, one may equate a measure of the space devoted to a topic with the importance a source attributes to it. The relation between different speech disturbances and the diagnosis of certain psychopathologies may be established by correlation. The relation between the proximity of words and associations, having been experimentally confirmed, may be operationalized in clustering algorithms that compute word clusters from strings of words.

While the evidential support for the intended inferences can come from anywhere, content analysts cannot bypass justifying this step. It would be methodologically inadmissible to claim to have analyzed *the* content of a certain news channel, as if no inference were made or as if content were obvious and unquestionably contained same for everyone, including content analysts. It is equally inadmissible to conclude from applying a standard coding instrument and a sound reliability statistic on the coded data, that its results relate to the many worlds of others. They may represent nothing other than the content analyst's systematized conceptions.

Regarding the analytical construct, content analysts face two tasks: preparatory and applied. Before designing

a content analysis, researchers may need to test or explore available evidence, including theories of the stable relations on grounds of which the use of analytical constructs can be justified. After processing the textual data, the inferences tendered will require similar justifications.

Interpretation

The result of an inference needs to be interpreted so as to select among the possible answers to the given research question. In identifying the author of an unsigned document, one may have to translate similarities between signed and unsigned documents into probabilities associated with conceivable authors. In predicting the use of a weapon system from enemy domestic propaganda, one may have to extrapolate the fluctuations of mentioning it into a set of dates. In ascertaining gender biases in educational material, one may have to transform the frequencies of gender references and their evaluation into weights of one gender over another.

Interpreting inferences in order to select among alternative answers to a research question can be quite rigorous. Merely testing hypotheses on the descriptive accounts of available texts stays within the impressionistic nature of these descriptions and has little to do with content analysis.

Criteria for Judging Results

There are essentially three conditions for judging the acceptability of content analysis results. In the absence of direct validating evidence for the inferences that content analysts make, there remain reliability and plausibility.

Reliability

Reliability is the ability of the research process to be replicated elsewhere. It is inferred from the agreement observed among several independently coded sets of phenomena and assures content analysts that their data represent the phenomena of analytical interest. It is meant to ensure that other researchers are able to replicate the process of generating these data and build on them. It allows critics to decode the data by reversing the given coding instructions. Empirically, the most unreliable part of a content analysis is the unitizing and scaling of phenomena and recoding interpretations of them in a provided code. A good deal of content analysts' work goes into making sure that coders, working independent of each other, agree on the application of the coding instruction so that their data are worth analyzing. Measures of reliability are provided by agreement

coefficients with suitable reliability interpretations, such as Scott's π (pi) and Krippendorff's α (alpha).

The literature contains recommendations regarding the minimum agreement required for an analytical process to be sufficiently reliable. However, that minimum should be a function of the probability of compromised data leading their content analyst to invalid results. Some disagreements among coders may not make a difference, but others could direct the process to invalid results.

Plausibility

Computer content analysts pride themselves in having bypassed reliability problems. However, all content analysts need to establish the plausibility of the path taken from texts to their results. This presupposes explicitness as to the analytical steps taken. The inability to critically examine the steps by which a content analysis proceeded to its conclusion introduces doubts in whether an analysis can be trusted. For example, claims to have used an algorithm that extracts meanings from text need to be questioned. Content analysts cannot hide behind obscure algorithms whose inferences are unclear. Plausibility may not be quantifiable, as reliability is, but it is one criterion all content analyses must satisfy.

Validity

In content analysis, validity may be demonstrated variously. The preferred validity is *predictive*, matching the answers to the research question with subsequently obtained facts. When direct and post facto validation is not possible, content analysts may need to rely on indirect evidence. For example, when inferring the psychopathology of a historical figure, accounts by the person's contemporaries, actions on record, or comparisons with today's norms may be used to triangulate the inferences. Similarly, when military intentions are inferred from the domestic broadcasts of wartime enemies, such intentions may be correlated with observable consequences or remain on record, allowing validation at a later time. *Correlative* validity is demonstrated when the results of a content analysis correlate with other variables. *Structural* validity refers to the degree to which the analytical construct employed adequately models the stable relations underlying the inferences, and *functional* validity refers to the history of the analytical construct's successes. *Semantic* validity concerns the validity of the description of textual matter relative to a designated group of readers, and *sampling* validity concerns the representativeness of the sampled text. Unlike in

observational research, texts need to be sampled in view of their ability to provide the answers to research questions, not necessarily to represent the typical content produced by their authors.

CONTENT VALIDITY

Content validity refers to the extent to which the items on a test are fairly representative of the entire domain the test seeks to measure. This entry discusses origins and definitions of content validation, methods of content validation, the role of content validity evidence in validity arguments, and unresolved issues in content validation.

Origins and Definitions

One of the strengths of content validation is the simple and intuitive nature of its basic idea, which holds that what a test seeks to measure constitutes a *content domain* and the items on the test should sample from that domain in a way that makes the test items representative of the entire domain. Content validation methods seek to assess this quality of the items on a test. Nonetheless, the underlying theory of content validation is fraught with controversies and conceptual challenges.

At one time, different forms of validation, and indeed validity, were thought to apply to different types of tests. Florence Goodenough made an influential distinction between tests that serve as *samples* and tests that serve as *signs*. From this view, personality tests offer the canonical example of tests as signs because personality tests do not sample from a domain of behavior that constitutes the personality variable but

rather serve to indicate an underlying personality trait. In contrast, educational achievement tests offer the canonical example of tests as samples because the items sample from a knowledge or skill domain, operationally defined in terms of behaviors that demonstrate that corresponding knowledge or skill that the test measures achievement in. For example, if an addition test contains items representative of all combinations of single digits, then it may adequately represent addition of single-digit numbers, but it would not adequately represent addition of numbers with more than one digit.

Jane Loevinger and others have argued that the above distinction does not hold up because all tests actually function as signs. The inferences drawn from test scores always extend beyond the test-taking behaviors themselves, but it is impossible for the test to include anything beyond test-taking behaviors. Even work samples can extend only to samples of work gathered within the testing procedure (as opposed to portfolios, which lack the standardization of testing procedures). To return to the above example, one does not use an addition test to draw conclusions only about answering addition items on a test but seeks to generalize to the ability to add in contexts outside addition tests.

At the heart of the above issue lies the paradigmatic shift from discrete forms of validity, each appropriate to one kind of test, to a more unified approach to test validation. The term *content validity* initially differentiated one form of validity from *criterion validity* (divisible into concurrent validity and predictive validity, depending on the timing of the collection of the criterion data) and *construct validity* (which initially referred primarily to the pattern of correlations with other variables, the *nomological net*, and to the pattern of association between the scores on individual items within the test). Each type of validity arose from a set of practices that the field developed to address a particular type of practical application of test use. Content validity was the means of validating tests used to sample a content domain and evaluate mastery within that domain. The *unified view of validity* initiated by Loevinger and Lee Cronbach, and elaborated by Samuel Messick, sought to forge a single theory of test validation that subsumed these disparate practices. (Followers of this unitary view sometimes object to referring to content-based validity as a “type” of validity for this reason.)

The basic practical concern involved the fact that assessment of the representativeness of the content domain achieved by a set of items does not provide a sufficient basis to evaluate the soundness of inferences from scores on the test. For example, a student correctly answering arithmetic items at a level above chance offers stronger support for the conclusion that he or she can do the arithmetic involved than the same

student failing to correctly answer the items offers for the conclusion that he or she cannot do the arithmetic. It may be that the student can correctly calculate 6 divided by 2 but has not been exposed to the $6 / 2$ notation used in the test items. In another context, a conscientious employee might be rated low on a performance scale because the items involve tasks that are important to and representative of the domain of conscientious work behaviors but opportunities for which come up extremely rarely in the course of routine work (e.g., reports defective equipment when encountered). Similarly, a test with highly representative items might have inadequate reliability or other deficiencies that reduce the validity of inferences from its scores. The traditional approach to dividing up types of validity and categorizing tests with respect to the appropriate type of validation tends in practice to encourage reliance on just one kind of validity evidence for a given test. Because just one type alone, including content-related validation evidence, does not suffice to underwrite the use of a test, the unified view sought to discourage such categorical typologies of either tests or validity types and replace these with validation methods that combined different forms of evidence for the validity of the same test.

As Stephen Sireci and others have argued, the problem with the unified approach with respect to content validation stems directly from this effort to improve on inadequate test validation practices. A central ethos of unified approaches involves the rejection of a simple checklist approach to validation, in which completion of a fixed set of steps results in a permanently validated test that requires no further research or evaluation. As an antidote to this checklist conception, Michael Kane and others elaborated the concept of a *validity argument*. The basic idea was that test validation involves building an argument that combines multiple lines of evidence of the overall evaluation of a use or interpretation of scores derived from a test. To avoid a checklist, the argument approach leaves it open to the test validator to exercise judgment and select the lines of evidence that are most appropriate in a given instance. This generally involves selecting the premises of the validation argument that bear the most controversy and for which empirical support can be gathered within practical constraints on what amounts to a reasonable effort. One would not waste resources gathering empirical evidence for claims that no one would question. Similarly, one would not violate ethical standards in order to validate a test of neural functioning by damaging various portions of the cortex in order to experimentally manipulate the variable with random assignment. Nor would one waste resources on an enormous and costly effort to test one assumption if

those resources could be better used to test several others in a less costly fashion. In short, the validity argument approach to test validation does not specify that any particular line of evidence is required of a validity argument. As a result, an effort to discourage reliance on content validation evidence alone may have swung the pendulum too far in the opposite direction by opening the door to validation efforts that exclude content validation where it could provide an important and perhaps necessary line of support. These considerations have led to proposals to modify the argument approach to validation in ways that make content-related evidence necessary or at least strongly recommended for tests based on sampling from a content domain.

Contemporary approaches to content validation typically distinguish various aspects of content validity. A clear *domain definition* is foundational for all the other aspects of content validity because without a clear definition of the domain, test developers, test users, or anyone attempting to do validation research has no basis for a clear assessment of the remaining aspects. This aspect of content validation closely relates to the emphasis in the *Standards for Educational and Psychological Testing* on clearly defining the purpose of a test as the first step in test validation.

A second aspect of content validity, *domain relevance*, draws a further connection between content validation and the intended purpose of the test. Once the domain has been defined, domain relevance describes the degree to which the defined domain bears importance to the purpose of the test. For example, one could imagine a test that does a very good job of sampling the skills required to greet visitors, identify whom they wish to see, schedule appointments, and otherwise exercise the judgment and complete the tasks required of an effective receptionist. However, if the test use involves selecting applicants for a back office secretarial position that does not involve serving as a receptionist, then the test would not have good domain relevance for the intended purpose. This aspect of content validation relates to a quality of the defined domain independent of how well the test taps that domain.

In contrast, *domain representation* does not evaluate the defined domain but rather evaluates the effectiveness with which the test samples that domain. Clearly, this aspect of content validation depends on the previous two. Strong content representation does not advance the quality of a test if the items represent a domain with low relevance. Furthermore, even if the items do represent a domain well, the test developer has no effective means of ascertaining that fact without a clear domain definition. Domain representation can suffer in two ways: Items on the test may fail to sample some portion of the test domain, in which case the

validity of the test suffers as a result of construct underrepresentation. Alternatively, the test might contain items from outside the test domain, in which case these items introduce construct-irrelevant variance into the test total score. It is also possible that the test samples all and only the test domain but does so in a way that overemphasizes some areas of the domain while underemphasizing other areas. In such a case, the items sample the entire domain but in a nonrepresentative manner. An example would be an addition test where 75% of the items involved adding only even numbers and no odd numbers.

An additional aspect of content validation involves clear, detailed, and thorough documentation of the test construction procedures. This aspect of content validation reflects the epistemic aspect of modern test validity theory: Even if a test provides an excellent measure of its intended construct, test users cannot justify the use of the test unless they know that the test provides an excellent measure. Test validation involves justifying an interpretation or use of a test, and content validation involves justifying the test domain and the effectiveness with which the test samples that domain. Documentation of the process leading to the domain definition and generation of the item pool provides a valuable source of content-related validity evidence. One primary element of such documentation, the *test blueprint*, specifies the various areas of the test domain and the number of items from each of those areas. Documentation of the process used to construct the test in keeping with the specified test blueprint thereby plays a central role in evaluating the congruency between the test domain and the items on the test.

The earlier passages of this entry have left open the question of whether content validation refers only to the items on the test or also to the processes involved in answering those items. Construct validation has its origins in a time when tests as the object of validation were not yet clearly distinguished from test scores or test score interpretations. As such, most early accounts focused on the items rather than the processes involved in answering them. Understood this way, content validation focuses on qualities of the test rather than qualities of test scores or interpretations. However, as noted above, even this test-centered approach to content validity remains relative to the purpose for which one uses the test. Domain relevance depends on this purpose, and the purpose of the test should ideally shape the conceptualization of the test domain. However, focus on just the content of the items allows for a broadening of content validation beyond the conception of a test as measuring a construct conceptualized as a latent variable representing a single dimension of variation. It allows, for instance, for a test domain that

spans a set of tasks linked another way but heterogeneous in the cognitive processes involved in completing them. An example might be the domain of tasks associated with troubleshooting a complex piece of technology such as a computer network. No one algorithm or process might serve to troubleshoot every problem in the domain, but content validation that held separate from response processes can nonetheless apply to such a test.

In contrast, the idea that content validity applies to response processes existed as a minority position for most of the history of content validation but has close affinities to both the unified notion of validation as an overall evaluation based on the sum of the available evidence and also with cognitive approaches to test development and validation. Whereas representativeness of the item content bears more on a quality of the stimulus materials, representativeness of the response processes bears more on an underlying individual differences variable as a property of the person tested. Susan Embretson has distinguished *construct representation*, involving the extent to which items require the cognitive processes that the test is supposed to measure, from *nomothetic span*, which is the extent to which the test bears the expected patterns of association with other variables (what Cronbach and Paul Meehl called *nomological network*). The former involves content validation applied to processes, whereas the latter involves methods more closely associated with criterion-related validation and construct validation methods.

Content Validation Methodology

Content-related validity evidence draws heavily from the test development process. The content domain should be clearly defined at the start of this process, *item specifications* should be justified in terms of this domain definition, *item construction* should be guided and justified by the item specifications, and the overall test blueprint that assembles the test from the item pool should also be grounded in and justified by the domain definition. Careful documentation of each of these processes provides a key source of validity evidence.

A standard method for assessing content validity involves judgments by *subject matter experts* (SMEs) with expertise in the content of the test. Two or more SMEs rate each item, although large or diverse tests may require different SMEs for different items. Ratings typically involve domain relevance or importance of the content in individual test items. Good items have high means and low standard deviations, indicating high agreement among raters. John Flanagan introduced a *critical incident technique* for generating and

evaluating performance-based items. C. H. Lawshe, Lewis Aiken, and Ronald Hambleton each introduced quantitative measures of agreement for use with criterion-related validation research. Victor Martuza introduced a *content validity index*, which has generated a body of research in the nursing literature. A number of authors have also explored multivariate methods for investigating and summarizing SME ratings, including factor analysis and multidimensional scaling methods. Perhaps not surprisingly, the results can be sensitive to the approach taken to structuring the judgment task.

Statistical analysis of item scores can also be used to evaluate content validity by showing that the content domain theory is consistent with the clustering of items into related sets of items by some statistical criteria. These methods include factor analysis, multidimensional scaling methods, and cluster analysis. Applied to content validation, these methods overlap to some degree with construct validation methods directed toward the internal structure of a test. Test developers most often combine such methods with methods based on SME ratings to lessen interpretational ambiguity of the statistical results.

A growing area of test validation related to content involves cognitive approaches to modeling the processes involved in answering specific item types. Work by Embretson and Robert Mislevy exemplifies this approach, and such approaches focus on the construct representation aspect of test validity described above. This methodology relies on a strong cognitive theory of how test takers process test items and thus applies best when item response strategies are relatively well understood and homogeneous across items. The approach sometimes bears a strong relation to the facet analysis methods of Louis Guttman in that item specifications describe and quantify a variety of item attributes, and these can be used to predict features of item response patterns such as item difficulty. This approach bears directly on content validity because it requires a detailed theory relating how items are answered to what the items measure. Response process information can also be useful in extrapolating from the measured content domain to broader inferences in applied testing, as described in the next section.

Role in Validity Arguments

At one time, the dominant approach was to identify certain tests as the type of test to which content validation applies and rely on content validity evidence for the evaluation of such tests. Currently, few, if any, scholars would advocate sole reliance on content validity evidence for any test. Instead, content-related evidence joins with other evidence to support key inferences and

assumptions in a validity argument that combines various sources of evidence to support an overall assessment of the test score interpretation and use.

Kane has suggested a two-step approach in which one first constructs an argument for test score interpretations and then evaluates that argument with a test validity argument. Kane has suggested a general structure involving four key inferences to which content validity evidence can contribute support. First, the prescribed scoring method involves an inference from observed test-taking behaviors to a specific quantification intended to contribute to measurement through an overall quantitative summary of the test takers' responses. Second, test score interpretation involves generalization from the observed test score to the defined content domain sampled by the test items. Third, applied testing often involves a further inference that extrapolates from the measured content domain to a broader domain of inference that the test does not fully sample. Finally, most applied testing involves a final set of inferences from the extrapolated level of performance to implications for actions and decisions applied to a particular test taker who earns a particular test score.

Statistical models used to provide criterion- and construct-related validity evidence almost always require content-related evidence of validity to support valid test score interpretations. While not a fixed foundation for inference, content-related evidence provides a strong basis for taking one interpretation of a nomothetic structure as more plausible than various rival hypotheses. As such, content-related validity evidence continues to play an important role in test development and complements other forms of validity evidence in validity arguments.

Unresolved Issues

As validity theory continues to evolve, a number of issues in content validation remain unresolved. For instance, the relative merits of restricting content validation to test content or expanding it to involve item response processes warrant further attention. A variety of aspects of content validity have been identified, suggesting a multidimensional attribute of tests, but quantitative assessments of content validity generally emphasize single-number summaries. Finally, the ability to evaluate content validity in real time with computer-adaptive testing remains an active area of research.

CONTINGENCY TABLE ANALYSIS

A contingency table is a table of counts, produced by cross-classifying items (e.g., persons, products, institutions) according to two or more *categorical* variables (attributes). Contingency tables group item-specific data in cells without losing information of the cross-classified variables, thus providing a summary presentation and a first descriptive analysis, aiming at examining the underlying associations among the classification variables. Contingency tables commonly occur in applications of psychological, educational, and social sciences. The information of a contingency table is further summarized by measures of association and analyzed by appropriate models.

The decision for the appropriate type of measures and models for a specific contingency table analysis relies on the nature of the study, the hypothesis under investigation, and the measurement scale of the classification variables (*nominal* or *ordinal*). Studies may target measuring and analyzing the effect of a set of explanatory variables on one or more response variables or may treat variables in a symmetric manner investigating the underlying association and interaction structures, in which case all variables are considered as response variables. Measures of association are

distinguished to *directional* and *nondirectional*, depending on whether a distinction between explanatory and response variables exists or not. Furthermore, measures for nominal variables refer only to the strength of the association, whereas for ordinal variables provide information also for its direction (positive or negative). The development of association measures was pioneering, the contribution of Leo A. Goodman and William H. Kruskal.

The standard models used for contingency tables analysis are the loglinear models that are applicable when all the classification variables are responses and interest lies on the underlying structure of dependencies (or conditional independencies) among them. When the focus is on modeling the effect of a set of categorical explanatory variables on a categorical response, then appropriate are the logit models, that is, logistic regression models, having all explanatory variables categorical. Both loglinear and logit models belong to the family of generalized lineal models (GLMs), introduced by John A. Nelder and Robert W. M. Wedderburn in 1972. The family of GLMs provides a powerful and flexible framework, since it unifies a broad set of models through the choice for the distribution of the random component and the link function. This way, procedures of statistical inference, model fit, and model selection are also unified and easily implemented in statistical software. GLMs facilitated the analysis of contingency tables and stimulated the further development of modeling options.

The analysis of high-dimensional sparse contingency tables is an interesting area rooting back in the 1980s and the pioneering work of Stephen E. Fienberg. He explored the role of maximum likelihood estimates (MLEs) and loglinear model selection and identified challenges related to statistical learning problems and actual applications such as analysis of social media data or mobility tables in social networks.

Two-Way Contingency Tables

Consider an $I \times J$ contingency table of observed frequencies $\mathbf{n} = (n_{ij})$, derived by cross-classifying two categorical variables, X and Y of I and J categories, respectively. We assume that $\mathbf{n}$ is a realization of a random table $\mathbf{N} = (N_{ij})$ of fixed total sample size $\sum_{i,j} N_{ij} = \sum_{i,j} n_{ij} = n$, which is multinomial distributed $\mathbf{N} \sim \text{Mult}(n, \boldsymbol{\pi})$, where $\boldsymbol{\pi} = (\pi_{ij})$ is the joint distribution of X and Y . The most common hypothesis of interest is that of independence of X and Y , expressed as

$$\pi_{ij} = P(X = i, Y = j) = P(X = i) \cdot P(Y = j) = \pi_{i+} \pi_{+j}, \quad (1)$$

$$i = 1, \dots, I, \quad j = 1, \dots, J,$$

where π_{ij} is the joint probability of $X = i$ and $Y = j$, while π_{i+} and π_{+j} the corresponding marginal probabilities. Hypothesis 1 is tested by the well-known test of independence of Karl Pearson, introduced in 1900. Under Hypothesis 1, the table of expected cell frequencies $\mathbf{m} = (m_{ij})$ has entries equal to $m_{ij} = n\pi_{ij} = n\pi_{i+}\pi_{+j}$, $i = 1, \dots, I$, $j = 1, \dots, J$. The corresponding MLEs equal $\hat{m}_{ij} = n\hat{\pi}_{i+}\hat{\pi}_{+j} = n \frac{n_{i+}}{n} \frac{n_{+j}}{n} = \frac{n_{i+}n_{+j}}{n}$, where $\hat{\pi}_{i+}$ ($\hat{\pi}_{+j}$) denotes the sample proportion in the i th row (j th column). The hypothesis of independence is then tested through Pearson's chi-square statistic:

$$\chi^2 = \sum_{i,j} \frac{(n_{ij} - \hat{m}_{ij})^2}{\hat{m}_{ij}}, \quad (2)$$

which under Hypothesis 1 is approximately $\chi^2_{(I-1)(J-1)}$ distributed, provided that the number of cells of the table is fixed and the expected cell frequencies are not too small. Hypothesis 1 is rejected at significance level α , if the observed value of the χ^2 test statistic in Equation 2 exceeds the $(1-\alpha)$ quantile of the $\chi^2_{(I-1)(J-1)}$ distribution.

2 × 2 Tables

The simplest contingency table is a 2×2 contingency table, derived for example by cross-classifying two independent groups according to a binary outcome (success–failure). The fundamental measure of association for 2×2 tables is the odds ratio (OR). For the probability table,

Group	Success	Failure
A	π_{11}	π_{12}
B	π_{21}	π_{22}

the Within-group A success probability equals $\pi_{1|A} = \pi_{1|I=1} = \frac{\pi_{11}}{\pi_{11} + \pi_{12}}$ and the odds of success for this group is $\pi_{1|A} / (1 - \pi_{1|A})$, with the odds of success being defined analogously for Group B. Then the OR is defined as:

$$\theta = \frac{\pi_{1|A} / (1 - \pi_{1|A})}{\pi_{1|B} / (1 - \pi_{1|B})} = \frac{\pi_{11} / \pi_{12}}{\pi_{21} / \pi_{22}} = \frac{\pi_{11}\pi_{22}}{\pi_{12}\pi_{21}}$$

and its ML estimate, based on an observed 2×2 table $\mathbf{n}$, is $\hat{\theta}(\mathbf{n}) = \frac{n_{11}n_{22}}{n_{12}n_{21}}$. For 2×2 tables, the hypothesis of independence (Equation 1) is equivalent to $\pi_{1|A} = \pi_{1|B}$, that is, to $\theta = 1$, which for large samples can be tested based on the asymptotic normality of the

ML estimator of θ , $\hat{\theta} = \hat{\theta}(\mathbf{N}) = \frac{N_{11}N_{22}}{N_{12}N_{21}}$, in log-scale, since it holds approximately

$$\log(\hat{\theta}) \sim N\left(\log(\theta), \frac{1}{n_{11}} + \frac{1}{n_{12}} + \frac{1}{n_{21}} + \frac{1}{n_{22}}\right).$$

Asymptotic confidence intervals for θ can easily be derived based on this approximation. If Group A indicates the presence of a factor and Group B its absence, then a value of $\theta > 1$ ($\theta < 1$) corresponds to positive (negative) association of the factor and the procedure under control. The strength of the association is increasing in $|\theta|$.

Loglinear Models

The model of independence (Equation 1) is equivalently expressed as a loglinear model:

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y, \quad i = 1, \dots, I, \quad j = 1, \dots, J,$$

where the parameters λ_i^X , $i = 1, \dots, I$, (λ_j^Y , $j = 1, \dots, J$) are the row (column) main effects, respectively. Some identifiability constraints need to be imposed on these parameters. Usually, a specific category effect is set to zero, the first ($\lambda_1^X = \lambda_1^Y = 0$) or the last ($\lambda_I^X = \lambda_J^Y = 0$). Alternatively, the sum to zero constraint can be applied

$$\left(\sum_i \lambda_i^X = \sum_j \lambda_j^Y = 0 \right).$$

The estimation and thus the fit of the model is not affected by the specific identifiability constraints used; these influence only the interpretation of the parameters, since they consider different reference points. For example, for $\lambda_1^Y = 0$, it holds $\lambda_j^Y = \log(m_{ij} / m_{i1})$, that is, $\exp(\lambda_j^Y)$ is the odds of the j th category of Y versus the first and, under independence, it is the same for all levels of X .

When the independence model is rejected, the association between X and Y is statistically significant and is captured by adding XY -interaction terms to the loglinear model presented earlier.

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_{ij}^{XY}, \quad i = 1, \dots, I, \quad j = 1, \dots, J. \quad (3)$$

Identifiability constraints, analogous to those of the main effects, apply also for the interactions. Model 3 has IJ parameters—that is, equal to the number of the cells—and is thus of perfect fit ($\hat{m}_{ij} = n_{ij}$, for all i, j). Such a model is called *saturated model*. The two-factor interaction terms are parameters capturing the association between X and Y at their specified levels and are expressed in terms of certain ORs.

The OR as a concept plays a central role in contingency table modeling and is extended for $I \times J$

tables to the generalized ORs. Any $I \times J$ probability table π with positive entries is uniquely determined by its row and column marginals, $\pi_r = (\pi_{1+}, \dots, \pi_{I+})'$ and $\pi_c = (\pi_{+1}, \dots, \pi_{+J})'$, and a minimal set of $(I-1) \times (J-1)$ generalized ORs. There exist various types of generalized ORs (e.g.); relevant to loglinear models are the local ORs. For an $I \times J$ contingency table, the minimal set of local ORs consists of the ORs, corresponding to all 2×2 subtables formed by successive rows and columns.

$$\theta_{ij} = \frac{\pi_{ij}\pi_{i+1,j+1}}{\pi_{i+1,j}\pi_{i,j+1}} = \frac{m_{ij}m_{i+1,j+1}}{m_{i+1,j}m_{i,j+1}}, \quad i = 1, \dots, I-1, \\ j = 1, \dots, J-1.$$

It can be easily verified that under Model 3, it holds $\log(\theta_{ij}) = \lambda_{ij}^{XY} + \lambda_{i+1,j+1}^{XY} - \lambda_{i+1,j}^{XY} - \lambda_{i,j+1}^{XY}$, while the model of independence can equivalently be expressed in terms of the local ORs as:

$$\log(\theta_{ij}) = 0, \quad i = 1, \dots, I-1, \quad j = 1, \dots, J-1. \quad (4)$$

So far we have assumed that the underlying sampling scheme of an observed contingency table $\mathbf{n}$ is multinomial. Alternatively, independent multinomial samples can be considered for each row of the table. In this case, all row marginals $n_{1+}, \dots, n_{I+}$ are fixed. Another commonly appearing sampling scheme is that of independent Poisson counts in each cell, that is, every n_{ij} is a realization of a random $N_{ij} \sim \text{Pois}(m_{ij})$. Under the last sampling scheme, the total sample size is random. However, on observing the sample, we can condition on the observed sample size n . Then, by conditioning on $\sum_{i,j} m_{ij} = n$, the independent Poisson sampling scheme becomes equivalent to the multinomial one with $\pi_{ij} = m_{ij} / n$, for all i, j . Hence the estimation and testing of models for contingency tables is the same for all three sampling schemes. Loglinear models can equivalently be expressed in terms of the cell probabilities. The usual choice is to define them in terms of expected frequencies because these are common for the different sampling schemes while the underlying probability structure is not.

Models for Ordinal Data

When independence is rejected, the saturated model is the only alternative in the standard loglinear models setup, which does not impose any structure on the underlying association. Structures of associations are imposed through association models (AMs). The uniform association model (U) is the simplest AM and

applies when both classification variables are ordinal. It assumes uniform local associations, that is, all local ORs are equal ($\theta_{ij} = \theta$ for all i, j). The U model is expressed as a loglinear model by assigning (known) scores, μ_i and ν_j , to the row and column categories, respectively, that are equidistant for successive categories (e.g., $\mu_i = i$, $\nu_j = j$). In particular, under model U, it holds

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y + \phi \mu_i \nu_j, \quad i = 1, \dots, I, \quad j = 1, \dots, J. \quad (5)$$

This model is the most parsimonious dependence model, having only one parameter more than the independence model, namely the parameter of intrinsic association ϕ . Consequently, the associated degrees of freedom are $(I-1)(J-1)-1$ and given that U holds, independence can be tested conditionally on it by testing $\phi = 0$ via a more powerful test with just one degree of freedom. More general AMs treat one or both sets of scores as parameters or even consider association terms

of higher (M th) order $\sum_{k=1}^M \phi_k \mu_{ik} \nu_{jk}$, with $1 \leq M \leq \min(I, J) - 1$. The later AMs are known as the RC(M) models. Models treating both sets of scores as parameters or having higher order association terms belong to the family of generalized nonlinear models.

Correspondence Analysis (CA)

CA is another method that studies the pattern of association between the row and column categories of a two-way contingency table assigning also scores to the row and column categories. CA is mainly descriptive and produces a reduced rank graphical display (two- or three-dimensional) of the underlying association captured by the assigned scores. CA models are linked to the RC(M) models (e.g., Kateri, 2014, chapter 7).

Logit Models

The logit models are relevant when one of the classification variables is a response and the other an explanatory variable. In case of a binary (success-failure) response Y and an explanatory variable X having I categories, they model the logit, which is

$$\log[P(Y = 1) / P(Y = 2)] = \beta_0 + \beta_i, \quad i = 1, \dots, I, \quad (6)$$

with identifiability constraint $\beta_1 = 0$. This can be derived from Equation 3 with $\beta_0 = \lambda_1^Y - \lambda_2^Y = -\lambda_2^Y$ and $\beta_i = \lambda_{i1}^{XY} - \lambda_{i2}^{XY} = -\lambda_{i2}^{XY}$, since $\log\left[\frac{P(Y = 1)}{P(Y = 2)}\right] = \log\left(\frac{m_{i1}}{m_{i2}}\right)$.

In case X is ordinal, a more parsimonious logit model can be defined by

$$\log[P(Y = 1) / P(Y = 2)] = \beta_0 + \beta \mu_i, \quad i = 1, \dots, I,$$

which is the logit expression of Equation 5 with $\beta = \phi(\nu_1 - \nu_2)$ and β_0 as defined earlier.

Logit models exist also for nominal and ordinal response variables with J categories. These models consist of a set of $J-1$ equations that simultaneously describe $J-1$ logits. For a nominal response Y and considering as reference category the last one, these logits are

$$\log[P(Y = 1) / P(Y = J)], \log[P(Y = 2) / P(Y = J)], \dots, \log[P(Y = J-1) / P(Y = J)].$$

For ordinal responses, more than one type of logits are possible; the most commonly used is defined in terms of cumulative probabilities

$$\log\left[\frac{P(Y \leq j)}{P(Y > j)}\right], \quad j = 1, \dots, J-1$$

(see McCullagh, 1980).

Square Tables

In case of cross-classifying categorical responses of matched pairs, a square $I \times I$ contingency table is derived with the same categories for rows and columns. Such tables occur in the study of rater agreement or social mobility. Hypotheses of interest in such cases are that of symmetry ($\pi_{ij} = \pi_{ji}$, $i, j = 1, \dots, I$) and marginal homogeneity (MH), that is, $\pi_{i+} = \pi_{+i}$, $i = 1, \dots, I$. MH for the 2×2 case of binary matched pairs is tested by the McNemar's test. Furthermore, under this setup, it is often of interest to model only the off-diagonal cells that correspond to pairs of different categories. For example, we want to model the disagreement of two raters or, in a social mobility application, to focus the analysis on pairs for which a change of status occurs. The most popular model of this type is that of quasi-independence (QI) under which the classification variables X and Y are independent, given that $X \neq Y$. In a rater agreement problem, QI would mean that, given that the two raters disagree, their ratings are independent, that is, there is no pattern of disagreement. Specific disagreement patterns, such as Rater A being constantly α times stricter than Rater B, can be captured by special symmetry models (conditional symmetry and diagonal symmetry). Another well-known model for square contingency table is the quasi-symmetry model.

Multiway Contingency Tables

All type of models discussed thus far extend to multidimensional tables. As the dimension of a table increases,

the number of available models also increases. In the framework of loglinear models, they may include higher order interactions up to interactions of order equal to the dimension of the table and vary in terms of the structure they impose on the underlying association among the classification variables. For a k -way table, the saturated model consists of all main effects and all possible interactions among the classification variables, from two-way up to k -way interactions.

For example, consider a realization of the cross-classification of random variables $X_1, \dots, X_5$, each having I_ℓ categories, $\ell = 1, \dots, 5$, to a five-way table of observed counts $\mathbf{n} = (n_{i_1 \dots i_5})$. Then, for $i_\ell = 1, \dots, I_\ell$, possible nonsaturated models are

$$\log(m_{i_1 \dots i_5}) = \lambda + \sum_{\ell=1}^5 \lambda_{i_\ell}^{X_\ell} + \lambda_{i_1 i_2}^{X_1 X_2} + \lambda_{i_3 i_5}^{X_3 X_5}, \quad (7)$$

$$\log(m_{i_1 \dots i_5}) = \lambda + \sum_{\ell=1}^5 \lambda_{i_\ell}^{X_\ell} + \lambda_{i_1 i_3}^{X_1 X_3} + \lambda_{i_1 i_5}^{X_1 X_5} + \lambda_{i_3 i_5}^{X_3 X_5}. \quad (8)$$

For higher dimensional contingency tables, the interpretation of the loglinear model interaction parameters is analog to the two-dimensional tables case. They describe conditional association among the variables involved and are based on conditional ORs. For example, under Model 7, the conditional OR comparing categories $i_3 \neq i'_3$ of X_3 for $X_5 = i_5$ vs. $X_5 = i'_5$ ($i_5 \neq i'_5$), given that the remaining variables are at fixed level, is given by

$$\begin{aligned} \log(\theta_{i_3 i'_3}^{i_5}) &= \frac{\pi_{i_1 i_2 i_3 i_4 i_5} \pi_{i_1 i_2 i'_3 i_4 i'_5}}{\pi_{i_1 i_2 i_3 i_4 i'_5} \pi_{i_1 i_2 i'_3 i_4 i_5}} \\ &= \lambda_{i_3 i_5}^{X_3 X_5} + \lambda_{i'_3 i'_5}^{X_3 X_5} - \lambda_{i_3 i'_5}^{X_3 X_5} - \lambda_{i'_3 i_5}^{X_3 X_5} \end{aligned}$$

and is the same for any fixed value of X_1, X_2 , and X_4 .

Model selection is a very important issue, since the number of possible models increases dramatically with the dimension of the table. In order to impose a structure on model building, we restrict to the family of hierarchical loglinear models. A model is hierarchical if whenever a higher order effect is in the model, then all possible lower order effects involving the variables of this higher order effect term are also included in the model. Such models are parsimoniously symbolized by the set of the highest order terms (with respect to all variables) that define them uniquely. Thus, equation 7 is hierarchical and denoted by $(X_4, X_1 X_2, X_3 X_5)$, whereas Model 8 is not hierarchical, since the $X_3 X_5$ interaction is missing. For model selection, standard methods that are available for GLMs can be adopted, such as stepwise methods based on the deviance or the Akaike information criterion.

In practice, there is often the tendency to analyze a high-dimensional contingency table by considering several lower dimensional tables derived by merging some variables. However, the association structure in these marginal tables can be quite different from the corresponding conditional association in which we control the variables instead of merging them. The Simpson's paradox can occur, that is, association may even change direction. The patterns of associations among variables and the identification of variables for which merging would be possible without affecting the underlying association structure can be visualized using graphical models. However, not all loglinear models are graphical models. The patterns of associations and their strengths in two- or multiway tables can also be illustrated through mosaic plots, which are special plots based on cell residuals corresponding to the fitted model. Other models discussed for two-way tables, such as AMs and CA, extend to multiway tables as well.

Loglinear models apply directly on the cell entries of a contingency table. In certain frameworks, it is of interest to model certain marginals of a table, since some structures are easier expressed in terms of marginal distributions. Marginal models for contingency tables impose structural restrictions on certain marginal of the classification variables and are usually of log-linear type. Marginal distributions modeling is important for *clustered* and *longitudinal* categorical data.

On Statistical Inference for Contingency Tables

Earlier in this entry, Pearson's chi-square test statistic (Equation 2) for testing asymptotically independence in a two-way table was provided. More generally, this test statistic can be applied for testing the goodness of fit of any model for two- or multiway tables, provided that the table of expected frequencies $\mathbf{m}$ can be estimated under the assumed model and that the required assumptions for the asymptotic chi-square distribution under the null hypothesis are fulfilled. Alternatively, the likelihood-ratio test can be applied, which is asymptotic equivalent to Pearson's chi-square, and is given for a two-way table by the equation:

$$G^2 = 2 \sum_{i,j} n_{ij} \log \left(\frac{n_{ij}}{\hat{m}_{ij}} \right).$$

In a GLM setup, the G^2 of a log-linear model fitted on a contingency table coincides with the deviance of the model and is used for conditional model selection between nested models.

The development of methods and algorithms for the analysis of contingency tables with small cell entries, for which asymptotic results are not applicable, has a

long history, starting with Fisher's exact test of independence for 2×2 tables. Beyond exact methods of analysis, a variety of simulation based approaches have also been proposed. Key algorithm for small sample contingency tables analysis is the algorithm of Cyrus R. Mehta and Nitin R. Patel for sampling from an $I \times J$ table with given marginals. Another option, especially useful for small samples inference, is to adopt a Bayesian approach (see Congdon, 2005).

In terms of estimation, the most commonly used method for contingency tables is ML while Bayesian estimation becomes increasingly popular, in which information from the data is combined with prior knowledge to obtain posterior distributions for the parameters of interest. For large samples, ML and Bayesian approaches yield similar results.

Implementation in Software

Standard statistical packages, such as SAS, SPSS, S-Plus, and the free software R (for statistical computing and graphics), are well equipped for analyzing contingency tables in the framework of GLMs or beyond. The Python module statsmodels also supports contingency table analysis approaches. Bayesian analysis of contingency tables can be carried out in special R-packages (e.g., bayesloglin, conting, MCMCpack) or through the WINBUGS software. Furthermore, specialized software is available. For example, StatXact from Cytel Software performs small sample exact analysis of contingency tables.

CONTRAST ANALYSIS

A standard analysis of variance (ANOVA) provides an F test, which is called an *omnibus test* because it reflects all possible differences between the means of the groups analyzed by the ANOVA. However, most experimenters want to draw conclusions more precise than “the experimental manipulation had an effect on the participants’ behavior.” Precise conclusions can be obtained from *contrast analysis* because a contrast expresses a specific question about the pattern of results of an ANOVA. Specifically, a contrast corresponds to a prediction precise enough to be translated into a set of numbers called *contrast coefficients*, which together reflect the prediction. The correlation between the contrast coefficients and the observed group means directly evaluates the similarity between the prediction and the results.

When performing a contrast analysis, one needs to distinguish whether the contrasts are planned or post hoc. Planned, or a priori, contrasts are selected before running the experiment. In general, they reflect the hypotheses the experimenter wanted to test, and there are usually *few* of them. Post hoc, or a posteriori (after the fact), contrasts are decided after the experiment has been run. The goal of a posteriori contrasts is to ensure that unexpected results are reliable.

When performing a planned analysis involving several contrasts, one needs to evaluate whether these contrasts are mutually orthogonal or not. Two contrasts are *orthogonal* when their contrast coefficients are uncorrelated (i.e., their coefficient of correlation is zero). The

number of possible orthogonal contrasts is one less than the number of levels of the independent variable.

All contrasts are evaluated by the same general procedure. First, the contrast is formalized as a set of contrast coefficients (also called *contrast weights*). Second, a specific F ratio (denoted F_ψ) is computed. Finally, the probability associated with F_ψ is evaluated. This last step changes with the type of analysis performed.

Research Hypothesis as a Contrast Expression

When a research hypothesis is precise, it is possible to express it as a contrast. A research hypothesis, in general, can be expressed as a shape, a configuration, or a rank ordering of the experimental means. In all these cases, one can assign numbers that will reflect the predicted values of the experimental means. These numbers are called *contrast coefficients* when their mean is zero. To convert a set of numbers into a contrast, it suffices to subtract their mean from each of them. Often, for convenience, contrast coefficients are expressed with integers.

For example, assume that for a four-group design, a theory predicts that the first and second groups should be equivalent, the third group should perform better than these two groups, and the fourth group should do better than the third with an advantage of twice the gain of the third over the first and the second. When translated into a set of ranks, this prediction gives

C_1	C_2	C_3	C_4	Mean
1	1	2	4	2

After subtracting the mean, we get the following contrast:

C_1	C_2	C_3	C_4	Mean
-1	-1	0	2	0

In case of doubt, a good heuristic is to draw the predicted configuration of results and then to represent the position of the means by ranks.

A Priori Orthogonal Contrasts For Multiple Tests

When several contrasts are evaluated, several statistical tests are performed on the same data set, and this increases the probability of a Type I error (i.e., rejection of the null hypothesis when it is true). In order to control the Type I error at the level of the set (also known as the *family*) of contrasts, one needs to correct

the α level used to evaluate each contrast. This correction for multiple contrasts can be done with the use of the Šidák equation, the Bonferroni (also known as *Boole* or *Dunn*) inequality, or the Monte Carlo method.

Šidák and Bonferroni

The probability of making *at least one* Type I error for a family of orthogonal (i.e., statistically independent) contrasts (C) is denoted $\alpha[\text{PF}]$, it is computed as

$$\alpha[\text{PF}] = 1 - (1 - \alpha[\text{PC}])^C. \quad (1)$$

Here, $\alpha[\text{PF}]$ is the Type I error for the family of contrasts and $\alpha[\text{PC}]$ is the Type I error *per* contrast. This equation can be rewritten as

$$\alpha[\text{PC}] = 1 - (1 - \alpha[\text{PF}])^{1/C}. \quad (2)$$

This formula, called the *Šidák equation*, shows how to correct the $[\text{PC}]$ values used for each contrast. Because the Šidák equation involves a fractional power, one can use an approximation known as the *Bonferroni inequality* (obtained from the first term of a Taylor expansion), which relates $\alpha[\text{PC}]$ to $\alpha[\text{PF}]$:

$$\alpha[\text{PC}] \approx \frac{\alpha[\text{PF}]}{C}. \quad (3)$$

Šidák and Bonferroni are related by the inequality:

$$\alpha[\text{PC}] = 1 - (1 - \alpha[\text{PF}])^{1/C} \geq \frac{\alpha[\text{PF}]}{C}. \quad (4)$$

These two equations give, in general, results very close to each other. As can be seen, the Bonferroni inequality is a pessimistic estimation. Consequently, Šidák should be preferred. However, the Bonferroni inequality is easier to compute and more well-known and hence it is used and cited more often.

Monte Carlo

The Monte Carlo technique can also be used to correct for multiple contrasts. The Monte Carlo technique consists of running a simulated experiment many times using random data, with the aim of obtaining a pattern of results showing what would happen just on the basis of chance. This approach can be used to quantify $\alpha[\text{PF}]$, the inflation of Type I error due to multiple testing. Equation 1 can then be used to set $\alpha[\text{PC}]$ in order to control the overall value of the Type I error.

As an illustration, suppose that six groups with 20 observations per group are created with data randomly sampled from a normal population. By construction, the H_0 is true (i.e., all population means are equal). Now, construct five *independent contrasts* from these six groups. For each contrast, compute an F test. If the

probability associated with the statistical index is smaller than $\alpha = .05$, the contrast is said to reach significance (i.e., $\alpha[\text{PC}]$ is used). Then have a computer redo the experiment a large number of times, here 100,000 times. In sum, there are 100,000 experiments, therefore 100,000 families of 5 contrasts each, and $5 \times 100,000 = 500,000$ contrasts total. The results of one such simulation are given in Table 1.

Table 1 shows that the H_0 is rejected for 24,969 contrasts of the 500,000 contrasts actually performed (i.e., 5 contrasts $\times$ 100,000 experiments). From these data, an estimation of $\alpha[\text{PC}]$ is computed as:

$$\begin{aligned}\alpha[\text{PC}] &= \frac{\text{Number of contrasts having reached significance}}{\text{Total number of contrasts}} \\ &= \frac{24,969}{500,000} = .04994.\end{aligned}\quad (5)$$

This value falls very close to the theoretical value of $\alpha = .05$.

It can be seen also that for 77,381 experiments, no contrast reached significance. Correspondingly, for 22,619 experiments (i.e., $100,000 - 77,381$), at least one Type I error was made. From these data, $\alpha[\text{PF}]$ can be estimated as:

$$\begin{aligned}\alpha[\text{PC}] &= \frac{\text{Number of families with at least 1 Type I error}}{\text{Total number of families}} \\ &= \frac{22,919}{100,000} = .22619.\end{aligned}\quad (6)$$

Table 1 Results of a Monte Carlo Simulation

<i>Number of Families With X Type I Errors</i>	<i>X: Number of Type 1 Errors per Family</i>	<i>Number of Type I Errors</i>
77,381	0	0
20,390	1	20,390
2,111	2	4,222
115	3	345
3	4	12
0	5	0
Total: 100,000		Total: 24,969

Note: Numbers of Type I errors when performing $C = 5$ contrasts for 100,000 analyses of variance performed on a six-group design when the H_0 is true. For example, 2,111 families of the 100,000 have two Type I errors. This gives $2 \times 2,111 = 4,222$ Type I errors.

This value falls close to the theoretical value given by Equation 1:

$$\alpha[\text{PF}] = 1 - (1 - \alpha[\text{PC}])^C = 1 - (1 - .05)^5 = .226.$$

Checking the Orthogonality of Two Contrasts

Two contrasts are orthogonal (or independent) if their contrast coefficients are uncorrelated. Contrast coefficients have zero sum (and therefore a zero mean). Therefore, two contrasts, whose A contrast coefficients are denoted $C_{a,1}$ and $C_{a,2}$, are orthogonal if and only if

$$\sum_{a=1}^A C_{a,i} C_{a,j} = 0. \quad (7)$$

Computing Sum of Squares, Mean Square, and F

The sum of squares for a contrast can be computed with the C_a coefficients. Specifically, the sum of square of ϕ is computed as:

$$SS_{\psi} = \frac{S(\sum C_a M_a)^2}{\sum C_a^2}, \quad (8)$$

where S is the number of subjects in a group and M_a is the mean of Group a .

Also, because the sum of squares for a contrast has one degree of freedom, it is equal to the mean square of effect for this contrast:

$$MS_{\psi} = \frac{SS_{\psi}}{df_{\psi}} = \frac{SS_{\psi}}{1} = SS_{\psi}. \quad (9)$$

The F_{ψ} ratio for a contrast is now computed as:

$$F_{\psi} = \frac{MS_{\psi}}{MS_{\text{error}}}. \quad (10)$$

Note incidentally that because the numerator of F (i.e., MS_{ϕ}) has only one degree of freedom, its square root is equal to a t -statistic, which is the statistic reported by some software.

Evaluating F for Orthogonal Contrasts

Planned orthogonal contrasts are equivalent to independent questions asked to the data. Because of that independence, the current procedure is to act as if each contrast was the only contrast tested: This amounts to *not* correcting for multiple tests. This procedure gives maximum power to the test. Practically, the null hypothesis for a contrast is tested by computing an F

ratio as indicated in Equation 10 and evaluating its p value using a Fisher sampling distribution with $v_1 = 1$ and v_2 being the number of degrees of freedom of MS_{error} , for example, in independent measurement designs with A groups and S observations per group, $v_2 = A(S-1)$.

Example

This example is inspired by an experiment that Steven M. Smith ran in 1979. The main purpose of this experiment was to show that one's being in the same mental context for learning and for testing leads to better performance than being in different contexts. During the learning phase, participants learned a list of 80 words in a room painted with an orange color, decorated with posters, paintings, and a large amount of paraphernalia. At the end of the learning phase, a memory test was performed to give subjects the impression that the experiment was over. One day later, the participants were unexpectedly retested on their memory. An experimenter asked them to write down all the words from the list that they could remember. The test took place in five different experimental conditions.

Fifty subjects (10 per group) were randomly assigned to one of the five experimental groups. The five experimental conditions were

- (1) *Same context.* Participants were tested in the same room in which they learned the list.
- (2) *Different context.* Participants were tested in a room very different from the one in which they learned the list. The new room was located in a different part of the campus, painted gray, and looked very austere.
- (3) *Imaginary context.* Participants were tested in the same room as participants from Group 2. In addition, they were told to try to remember the room in which they learned the list. In order to help them, the experimenter asked them several questions about the room and the objects in it.
- (4) *Photographed context.* Participants were placed in the same condition as Group 3, and in addition, they were shown photos of the orange room in which they learned the list.
- (5) *Placebo context.* Participants were in the same condition as participants in Group 2. In addition, before starting to try to recall the words, they asked

to perform a warm-up task, namely to try to remember their living room.

The data and ANOVA results of the replication of Smith's experiment are given in Tables 2 and 3.

Research Hypotheses for Contrast Analysis

Several research hypotheses can be tested with Smith's experiment. Suppose that the experiment was designed to test these hypotheses:

- *Research Hypothesis 1.* Groups for which the context at test matches the context during learning (i.e., is the same or is simulated by imaging or photography) will perform better than groups with different or placebo contexts.
- *Research Hypothesis 2.* The group with the same context will differ from the group with imaginary or photographed contexts.
- *Research Hypothesis 3.* The imaginary context group differs from the photographed context group.
- *Research Hypothesis 4.* The different context group differs from the placebo group.

Contrasts

The four research hypotheses are easily transformed into statistical hypotheses. For example, the first research hypothesis is equivalent to stating the following null hypothesis: The means of the population for Groups 1, 3, and 4 have the same value as the means of

the population for Groups 2 and 5. This is equivalent to contrasting Groups 1, 3, and 4, on one hand, and Groups 2 and 5, on the other. This first contrast is denoted ψ_1 :

$$\psi_1 = 2\mu_1 - 3\mu_2 + 2\mu_3 + 2\mu_4 + 3\mu_5.$$

The null hypothesis to be tested is

$$H_{0,s1} : \psi_1 = 0.$$

This first contrast is equivalent to defining the following set of coefficients C_a :

Gr.1	Gr.2	Gr.3	Gr.4	Gr.5	$\sum_a^A C_a$
+2	-3	+2	+2	-3	0

Note that the sum of the coefficients C_a is zero, as it should be for a contrast. Table 4 shows all four contrasts.

Are the Contrasts Orthogonal?

Now the problem is to decide whether the contrasts constitute an orthogonal family. We check that every pair of contrasts is orthogonal by using Equation 7. For example, Contrasts 1 and 2 are orthogonal because

$$\begin{aligned} \sum_{a=1}^A C_{a,1}c_{a,2} &= (2 \times 2) + (-3 \times 0) + (2 \times -1) + (-3 \times 0) + (0 \times 0) \\ &= 4 - 4 = 0. \end{aligned}$$

Table 5 Steps for the Computation of SS_{cI} of Smith (1979)

Group	M_a	C_a	$C_a M_a$	C_a^2
1	18.00	+2	+36.00	4
2	11.00	-3	-33.00	9
3	17.00	+2	+34.00	4
4	19.00	+2	+38.00	4
5	10.00	-3	-30.00	9
		0	45.00	30

Source: Adapted from Smith (1979).

F test

The sum of squares and F_ψ for a contrast are computed from Equations 8 and 10. For example, the steps for the computations of SS _{ψ_1} are given in Table 5.

$$SS_{\psi_1} = \frac{S(\sum C_a M_a)^2}{\sum C_a^2} = \frac{10 \times (45.00)^2}{30} = 675.00$$

$$MS_{\psi_1} = 675.00$$

$$F_{\psi_1} = \frac{MS_{\psi_1}}{MS_{\text{error}}} = \frac{675.00}{32.00} = 21.094$$

The significance of a contrast is evaluated with a Fisher distribution with 1 and $A(S-1) = 45$ degrees of freedom, which gives a critical value of 4.06 for $\alpha = 0.5$ (7.23 for $\alpha = .01$).

The sums of squares for the remaining contrasts are SS _{ψ_2} = 0, SS _{ψ_3} = 20, and SS _{ψ_4} = 5 with 1 and $A(S-1) = 45$ degrees of freedom. Therefore, ψ_2 , ψ_3 , and ψ_4 are nonsignificant. Note that the sums of squares of the contrasts add up to SS_{experimental}. That is,

$$SS_{\text{experimental}} = SS_{\psi_1} + SS_{\psi_2} + SS_{\psi_3} + SS_{\psi_4} = 675.00 + 0.00 + 20.00 + 5.00 = 700.00.$$

When the sums of squares are orthogonal, the degrees of freedom are added the same way as the sums of squares are. This explains why the maximum number of orthogonal contrasts is equal to the

number of degrees of freedom of the experimental sum of squares.

A Priori Nonorthogonal Contrasts

So orthogonal contrasts are relatively straightforward because each contrast can be evaluated on its own. Nonorthogonal contrasts, however, are more complex. The main problem is to assess the importance of a given contrast conjointly with the other contrasts. There are currently two (main) approaches to this problem. The classical approach corrects for multiple statistical tests (e.g., using a Šidák or Bonferroni correction) but essentially evaluates each contrast as if it were coming from a set of orthogonal contrasts. The multiple regression (or modern) approach evaluates each contrast as a predictor from a set of nonorthogonal predictors and estimates its *specific* contribution to the explanation of the dependent variable. The classical approach evaluates each contrast for itself, whereas the multiple regression approach evaluates each contrast as a member of a set of contrasts and estimates the specific contribution of each contrast in this set. For an orthogonal set of contrasts, the two approaches are equivalent.

The Classical Approach

Some problems are created by the use of multiple nonorthogonal contrasts. The most important one is that the greater the number of contrasts, the greater the risk of a Type I error. The general strategy adopted by the classical approach to this problem is to correct for multiple testing.

Šidák and Bonferroni Corrections

When a family's contrasts are nonorthogonal, Equation 10 gives a lower bound for $\alpha[\text{PC}]$. So instead of having the equality, the following inequality, called the *Šidák inequality*, holds:

$$\alpha[\text{PF}] \leq 1 - (1 - \alpha[\text{PC}])^C. \quad (12)$$

This inequality gives an upper bound for $\alpha[\text{PF}]$, and therefore the real value of $\alpha[\text{PF}]$ is smaller than its estimated value.

Table 6 Nonorthogonal Contrasts for the Replication of Smith (1979)

Contrast	Group 1	Group 2	Group 3	Group 4	Group 5	PCa
y1	2	-3	2	2	-3	0
y2	3	3	-2	-2	-2	0
y3	1	-4	1	1	1	0

Source: Adapted from Smith (1979).

As earlier, we can approximate the Šidák inequality by Bonferroni as

$$\alpha[\text{PF}] < C\alpha[\text{PC}]. \quad (13)$$

And, as earlier, Šidák and Bonferroni are linked to each other by the inequality:

$$\alpha[\text{PF}] \leq 1 - (1 - \alpha[\text{PC}])^C < C\alpha[\text{PC}]. \quad (14)$$

Example

Go back to Smith's (1979) study (see Table 2). Suppose that Smith wanted to test these three hypotheses:

- *Research Hypothesis 1.* Groups for which the context at test matches the context during learning will perform better than groups with different contexts.
- *Research Hypothesis 2.* Groups with real contexts will perform better than those with imagined contexts.
- *Research Hypothesis 3.* Groups with any context will perform better than those with no context.

These hypotheses can easily be transformed into the set of contrasts given in Table 6. The values of F_ψ were computed with Equation 10 (see also Table 3) and are shown in Table 7, along with their p values. If we adopt a value of $\alpha[\text{PF}] = .05$, a Šidák correction will entail evaluating each contrast at the α level of $\alpha[\text{PF}] = .0170$ (Bonferroni will give the approximate value of $\alpha[\text{PF}] = .0167$). So with a correction for multiple comparisons, one can conclude that Contrasts 1 and 3 are significant.

Multiple Regression Approach

ANOVA and multiple regression are equivalent if one uses as many predictors for the multiple regression analysis as the number of degrees of freedom of the independent variable. An obvious choice for the predictors is to use a set of contrast coefficients. Doing so makes contrast analysis a particular case of multiple regression analysis. When used with a set of orthogonal

contrasts, the multiple regression approach gives the same results as the ANOVA-based approach previously described. When used with a set of *nonorthogonal* contrasts, multiple regression quantifies the *specific* contribution of each contrast as the semipartial coefficient of correlation between the contrast coefficients and the dependent variable. The multiple regression approach can be used for nonorthogonal contrasts as long as the following constraints are satisfied:

- (1) There are no more contrasts than the number of degrees of freedom of the independent variable.
- (2) The set of contrasts is linearly independent (i.e., not multicollinear). That is, no contrast can be obtained by combining the other contrasts.

Example

Going back once again to Smith's (1979) study of learning and recall contexts. Suppose one takes the three contrasts (see Table 6) and uses them as predictors with a standard multiple regression program. One will find the following values for the semipartial correlation between the contrasts and the dependent variable:

$$\psi_1 : r_{Y.C_{a,1}|C_{a,2}C_{a,3}}^2 = .1994$$

$$\psi_2 : r_{Y.C_{a,2}|C_{a,1}C_{a,3}}^2 = .0000$$

$$\psi_3 : r_{Y.C_{a,3}|C_{a,1}C_{a,2}}^2 = .0013,$$

with $r_{Y.C_{a,1}|C_{a,2}C_{a,3}}^2$ being the squared correlation of ψ_1 and the dependent variable with the effects of ψ_2 and ψ_3 partialled out. To evaluate the significance of each contrast, we compute an F ratio for the corresponding semipartial coefficients of correlation. This is done with the following formula:

$$F_{Y.C_{a,j}|C_{a,k}C_{a,\ell}} = \frac{r_{Y.C_{a,j}|C_{a,k}C_{a,\ell}}^2}{1 - r_{Y.A}^2} \times df_{\text{residual}}. \quad (15)$$

This results in the following F ratios for the Smith example:

$$\psi_1 : F_{Y.C_{a,1}|C_{a,2}C_{a,3}} = 13.3333, \quad p = .0007;$$

$$\psi_2 : F_{Y.C_{a,2}|C_{a,1}C_{a,3}} = 0.0000, \quad p = 1.0000;$$

$$\psi_3 : F_{Y.C_{a,3}|C_{a,1}C_{a,2}} = 0.0893, \quad p = .7665.$$

These F ratios follow a Fisher distribution with $v_1 = 1$ and $v_2 = 45$ degrees of freedom. $F_{\text{critical}} = 4.06$ when $\alpha = .05$. In this case, ψ_1 is the only contrast reaching significance (i.e., with $F_\psi > F_{\text{critical}}$). The comparison with the classic approach shows the drastic differences between the two approaches.

Table 7 F_ψ Values for the Nonorthogonal Contrasts From the Replication of Smith (1979)

Contrast	r_Y	r_Y^2	F	pF
ψ_1	.9820	.9643	21.0937	<.0001
ψ_2	-.1091	.0119	0.2604	.6123
ψ_3	.5345	.2857	6.2500	.0161

Source: Adapted from Smith (1979).

A Posteriori Contrasts

For a posteriori contrasts, the family of contrasts is composed of all the possible contrasts even if they are not explicitly made. Indeed, because one chooses one of the contrasts to be made a posteriori, this implies that one has *implicitly* made and judged uninteresting *all* the possible contrasts that have not been made but *could* have been made. Hence, whatever the number of contrasts actually performed, the family is composed of all the possible contrasts. And, this number grows very fast: A conservative estimate indicates that the number of contrasts that can be made on A groups is equal to

$$1 + \{[(3^A - 1) / 2] - 2^A\}. \quad (16)$$

So, using a Šidák or Bonferroni approach with a posteriori contrasts will, in general, not have enough power to be useful.

Scheffé's Test

Scheffé's test was devised to test all possible contrasts a posteriori while maintaining the overall Type I error level for the family at a reasonable level, as well as trying to have a conservative but relatively powerful test. The general principle is to ensure that no discrepant statistical decision can occur. A discrepant decision would occur if the omnibus test would fail to reject the null hypothesis, but one a posteriori contrast could be declared significant.

To avoid such a discrepant decision, the Scheffé approach first tests any contrast as if it were the largest possible contrast whose sum of squares is equal to the experimental sum of squares (this contrast is obtained when the contrast coefficients are equal to the deviations of the group means to their grand mean) and, second, makes the test of the largest contrast equivalent to the ANOVA omnibus test. So if we denote by $F_{\text{critical, omnibus}}$ the critical value for the ANOVA omnibus test (performed on A groups), the largest contrast is equivalent to the omnibus test if its F_{ψ} is tested against a critical value equal to

$$F_{\text{critical, Scheffé}} = (A - 1) \times F_{\text{critical, omnibus}}. \quad (17)$$

Equivalently, F_{ψ} can be divided by $(A - 1)$, and its probability can be evaluated with a Fisher distribution with $\nu_1 = (A - 1)$ and ν_2 being equal to the number of degrees of freedom of the mean square error. Doing so makes it *impossible* to reach a discrepant decision.

An Example: Scheffé

Suppose that the F_{ψ} ratios for the contrasts computed in Table 7 were obtained a posteriori. The critical

value for the ANOVA is obtained from a Fisher distribution with $\nu_1 = A - 1 = 4$ and $\nu_2 = A(S - 1) = 45$. For $\alpha = .05$, this value is equal to $F_{\text{critical, omnibus}} = 2.58$. To evaluate whether any of these contrasts reaches significance, one needs to compare them to the critical value of

$$F_{\text{critical, Scheffé}} = (A - 1) \times F_{\text{critical, omnibus}} = 4 \times 2.58 = 10.32. \quad (18)$$

With Scheffé's approach, only the first contrast is considered significant.

CONTROL GROUP

In experimental research, it is important to confirm that results of a study are actually due to an independent or manipulated variable rather than to other, extraneous variables. In the simplest case, a research study contrasts two groups, and the independent variable is present in one group but not the other. For example, in a health research study, one group may receive a medical treatment, and the other does not. The first group, in which treatment occurs, is called the *experimental group*, and the second group, in which treatment is withheld, is called the *control group*. Therefore, when experimental studies use control and experimental groups, ideally the groups are equal on all factors except the independent variable. The purpose, then, of a control group is to provide a comparative standard in order to determine whether an effect has taken place in the experimental group. As such, the term *control group* is sometimes used interchangeably with the term *baseline group* or *contrast group*. The following discussion outlines key issues and several varieties of control groups employed in experimental research.

Random Assignment

In true experiments, subjects are assigned randomly to either a control or an experimental group. If the groups are alike in all ways except for the treatment administered, then the effects of that treatment can be tested without ambiguity. Although no two groups are exactly alike, random assignment, especially with large numbers, evens differences out. By and large, randomized group assignment results in groups that are equivalent, with the exception of the independent variable, or treatment of interest.

Placebo Control Groups

A *placebo* is a substance that appears to have an effect but is actually inert. When individuals are part of a placebo control group, they believe that they are receiving an effective treatment, when it is in fact a placebo. An example of a placebo study might be found in medical research in which researchers are interested in the effects of a new medication for cancer patients. The experimental group would receive the treatment under investigation, and the control group might receive an inert substance. In a double-blind placebo study, neither the participants nor the experimenters know who received the placebo until the observations are complete. Double-blind procedures are used to prevent experimenter expectations or experimenter bias from influencing observations and measurements.

Another type of control group is called a waiting list control. This type of control group is often used to assess the effectiveness of a treatment. In this design, all participants may experience an independent variable, but not at the same time. The experimental group receives a treatment and is then contrasted, in terms of the effects of the treatment, with a group awaiting treatment. For example, the effects of a new treatment for depression may be assessed by comparing a treated group, that is, the experimental group, with individuals who are on a wait list for treatment. Individuals on the wait list control may be treated subsequently.

When participants in an experimental group experience various types of events or participate for varying times in a study, the control group is called a *yoked control group*. Each participant of the control group is “yoked” to a member of the experimental group. As an illustration, suppose a study is interested in assessing the effects of students’ setting their own learning goals. Participants in this study might be yoked on the instructional time that they receive on a computer. Each participant in the yoked control (no goal setting) would be yoked to a corresponding student in the experimental group on the amount of time he or she spent on learning from the computer. In this way, the amount of

instruction experienced is held constant between the groups.

Matching procedures are similar to yoking, but the matching occurs on characteristics of the participant, not the experience of the participant during the study. In other words, in matching, participants in the control group are matched with participants in the experimental group so that the two groups have similar backgrounds. Participants are often matched on variables such as age, gender, and socioeconomic status. Both yoked and matched control groups are used so that participants are as similar as possible.

Ethics in Control Groups

The decision regarding who is assigned to a control group has been the topic of ethical concerns. The use of placebo controlled trials is particularly controversial because many ethical principles must be considered. The use of a wait-list control group is generally viewed as a more ethical approach when examining treatment effects with clinical populations. If randomized control procedures were used, a potentially effective treatment would have to be withheld. The harm incurred from not treating patients in a control group is usually determined, on balance, to be greater than the added scientific rigor that random assignment might offer.

Developed by the World Medical Association, the Declaration of Helsinki is an international document that provides the groundwork for general human research ethics. Generally, the guiding principle when one is using control groups is to apply strict ethical standards so that participants are not at risk of harm. Overall, the ethics involved in the use of control groups depends on the context of the scientific question.

CONTROL VARIABLES

In experimental and observational design and data analysis, the term *control variable* refers to variables that are not of primary interest (i.e., neither the exposure nor the outcome of interest) and thus constitute an extraneous or third factor whose influence is to be controlled or eliminated. The term refers to the investigator's desire to estimate an effect (such as a measure of association) of interest that is independent of the influence of the extraneous variable and free from bias arising from differences between exposure groups in that third variable.

Extraneous variables of this class are usually those variables described as potential confounders in some disciplines. Controlling for a potential confounder, which is not an effect modifier or mediator, is intended to isolate the effect of the exposure of interest on the outcome of interest while reducing or eliminating potential bias presented by differences in the outcomes observed between exposed and unexposed individuals that are attributable to the potential confounder. Control is achieved when the potential confounder cannot vary between the exposure groups, and thus the observed relationship between the exposure and outcome of interest is independent of the potential confounder.

As an example, if an investigator is interested in studying the rate of a chemical reaction (the outcome) and how it differs with different reagents (the exposures), the investigator may choose to keep the temperature of each reaction constant among the different reagents being studied so that temperature differences could not affect the outcomes.

Potential control variables that are mediators in another association of interest, as well as potential control variables that are involved in a statistical reaction with other variables in the study, are special cases which must be considered separately. This entry discusses the use of control variables during the design and analysis stages of a study.

Design Stage

There are several options for the use of control variables at the design stage. In the example about rates of reaction mentioned earlier, the intention was to draw conclusions, at the end of the series of experiments, regarding the relationship between the reaction rates and the various reagents. If the investigator did not keep the temperature constant among the series of experiments, difference in the rate of reaction found at the conclusion of the study may have had nothing to do

with different reagents, but be solely due to differences in temperature or some combination of reagent and temperature. Restricting or specifying a narrow range of values for one or more potential confounders is frequently done in the design stage of the study, taking into consideration several factors, including ease of implementation, convenience, simplified analysis, and expense. A limitation on restriction may be an inability to infer the relationship between the restricted potential confounder and the outcome and exposure. In addition, residual bias may occur, owing to incomplete control (referred to as *residual confounding*).

Matching is a concept related to restriction. Matching is the process of making the study group and control group similar with regard to potential confounds. Several different methods can be employed, including *frequency matching*, *category matching*, *individual matching*, and *caliper matching*. As with restriction, the limitations of matching include the inability to draw inferences about the control variable(s). Feasibility can be an issue, given that a large pool of subjects may be required to find matches. In addition, the potential for residual confounding exists.

Both matching and restriction can be applied in the same study design for different control variables.

The Analysis Stage

There are several options for the use of control variables at the analysis stage. Separate analysis can be undertaken for each level of a potential confounder. Within each unique value (or homogeneous stratum) of the potential confounder, the relationship of interest may be observed that is not influenced by differences between exposed and unexposed individuals attributable to the potential confounder. This technique is another example of restriction.

Estimates of the relationship of interest independent of the potential confounder can also be achieved by the use of a matched or stratified approach in the analysis. The estimate of interest is calculated at all levels (or several theoretically homogeneous or equivalent strata) of the potential confounder, and a weighted, average effect across strata is estimated. Techniques of this kind include the *Mantel-Haenszel stratified analysis*, as well as stratified (also called matched or conditional) regression analyses. These approaches typically assume that the stratum-specific effects are not different (i.e., no effect modification or statistical interaction is present). Limitations of this method are related to the various ways strata can be formed for the various potential confounders, and one may end up with small sample sizes in many strata, and therefore the analysis may not produce a reliable result.

The most common analytic methods for using control variables is analysis of covariance and multiple generalized linear regression modeling. Regression techniques estimate the relationship of interest conditional on a fixed value of the potential confounder, which is analogous to holding the value of the potential confounder constant at the level of third variable. By default, model parameters (intercept and beta coefficients) are interpreted as though potential confounders were held constant at their zero values. Multivariable regression is relatively efficient at handling small numbers and easily combines variables measured on different scales.

Where the potential control variable in question is involved as part of a statistical interaction with an exposure variable of interest, holding the control variable constant at a single level through restriction (in either the design or analysis) will allow estimation of the effect of the exposure of interest and the outcome that is independent of the third variable, but the effect measured applies only to (or is conditional on) the selected level of the potential confounder. This would also be the stratum-specific or conditional effect. For example, restriction of an experiment to one gender would give the investigator a gender-specific estimate of effect.

If the third variable in question is part of a true interaction, the other forms of control, which permit multiple levels of the third variable to remain in the study (e.g., through matching, statistical stratification, or multiple regression analysis), should be considered critically before being applied. Each of these approaches ignores the interaction and may serve to mask its presence.

CONVENIENCE SAMPLING

Few terms or concepts in the study of research design are as self-explanatory as convenience sampling. Convenience sampling (sometimes called *accidental sampling*) is the selection of a sample of participants from a population based on how convenient and readily available that group of participants is. It is a type of nonprobability sampling that focuses on a sample that is easy to access and readily available. For example, if one were interested in knowing the attitudes of a group of 1st-year college students toward binge drinking, a convenience sample would be those students enrolled in an introductory biology class.

The advantages of convenience sampling are clear. Such samples are easy to obtain, and the cost of obtaining them is relatively low. The disadvantages of convenience sampling should be equally clear. Results from studies using convenience sampling are not very generalizable to other settings, given the narrow focus of the technique. For example, using those biology 101 students would not only limit the sample to 1st-year students in that class, but also to those students enrolled in biology and all their characteristics. However, in spite of any shortcomings, convenience sampling is still an effective tool to use in pilot settings, when instruments may still be under development and interventions are yet to be fully designed and approved.

“CONVERGENT AND DISCRIMINANT VALIDATION BY THE MULTITRAIT–MULTIMETHOD MATRIX”

Psychology as an empirical science depends on the availability of valid measures of a construct. Validity means that a measure (e.g., a test or questionnaire) adequately assesses the construct (trait) it intends to measure. In their 1959 article “Convergent and Discriminant Validation by the Multitrait–Multimethod Matrix,” Donald T. Campbell and Donald W. Fiske proposed a way to test validation based on the idea that it is not sufficient to consider a single operationalization of a construct but that multiple measures are necessary. In order to validate a measure, scientists first have to define the construct to be measured in a literary form and then must generate at least two measures that are as different as possible but that are each adequate for measuring the construct (*multiple operationalism* in contrast to *single operationalism*). These two measures should strongly correlate but differ from measures that were created to assess different traits.

Campbell and Fiske distinguished between four aspects of the validation process that can be analyzed by means of the multitrait–multimethod (MTMM) matrix. First, convergent validity is proven by the correlation of independent measurement procedures for measuring the same trait. Second, new measures of a trait should show low correlations with measures of other traits from which they should differ (discriminant validity). Third, each test is a trait–method unit. Consequently, interindividual differences in test scores can be due to measurement features, as well as to the content of the trait. Fourth, in order to separate method- from trait-specific influences, and to analyze discriminant validity, more than one trait and more than one method have to be considered in the validation process.

Convergent Validity

Convergent validity evidence is obtained if the correlations of independent measures of the same trait (monotrait–heteromethod correlations) are significantly different from 0 and sufficiently large. Convergent validity differs from reliability in the type of methods considered. Whereas reliability is proven by correlations of maximally similar methods of a trait (monotrait–monomethod correlations), the proof of convergent validity is stronger, the more independent the methods are. For example, reliability of a self-report extroversion questionnaire can be analyzed by the correlations of two test halves of this questionnaire (*split-half reliability*)

whereas the convergent validity of the questionnaire can be scrutinized by its correlation with a peer report of extroversion. According to Campbell and Fiske, independence of methods is a matter of degree, and they consider reliability and validity as points on a continuum from reliability to validity. Heterotrait–monomethod correlations that do not significantly differ from 0 or are relatively low could indicate that one of the two measures or even both measures do not appropriately measure the trait (low convergent validity). However, a low correlation could also show that the two different measures assess different components of a trait that are functionally different. For example, a low correlation between an observational measure of anger and the self-reported feeling component of anger could indicate individuals who regulated their visible anger expression. In this case, a low correlation would not indicate that the self-report is an invalid measure of the feeling component and that the observational measure is an invalid indicator of overt anger expression. Instead, the two measures could be valid measures of the two different components of the anger episode that they are intended to measure, and different methods may be necessary to appropriately assess these different components. It is also recommended that one consider traits that are as independent as possible. If two traits are considered independent, the heterotrait–monomethod correlations should be 0. Differences from 0 indicate the degree of a common method effect.

Discriminant Validity

Discriminant validity evidence is obtained if the correlations of variables measuring different traits are low. If two traits are considered independent, the correlations of the measures of these traits should be 0. Discriminant validity requires that both the heterotrait–heteromethod correlations (e.g., correlation of a self-report measure of extroversion and a peer report measure of neuroticism) and the heterotrait–monomethod correlations (e.g., correlations between self-report measures of extroversion and neuroticism) be small. These heterotrait correlations should also be smaller than the monotrait–heteromethod correlations (e.g., self and peer report correlations of extroversion) that indicate convergent validity. Moreover, the patterns of correlations should be similar for the monomethod and the heteromethod correlations of different traits.

Impact

According to Robert J. Sternberg, Campbell and Fiske’s article is the most often cited paper that has ever been published in *Psychological Bulletin* and is

one of the most influential publications in psychology. In an overview of then-available MTMM matrices, Campbell and Fiske concluded that almost none of these matrices fulfilled the criteria they described. Campbell and Fiske considered the validation process as an iterative process that leads to better methods for measuring psychological constructs, and they hoped that their criteria would contribute to the development of better methods. However, 33 years later, in 1992, they concluded that the published MTMM matrices were still unsatisfactory and that many theoretical and methodological questions remained unsolved. Nevertheless, their article has had an enormous influence on the development of more advanced statistical methods for analyzing the MTMM matrix, as well as for the refinement of the validation process in many areas of psychology.

CONVERSATION ANALYSIS

This entry introduces conversation analysis (CA)—a qualitative methodology that originally arose within American sociology. CA is a methodological approach that focuses on the study of social interactions, with a particular emphasis on the orderly and sequential nature of talk. CA aims to study how people make sense of and respond to one another, as researchers using CA assume that people perform social activities through their language use. As such, CA gives particular attention to the organization of talk and examines how conversational turns are designed to perform particular

social actions (e.g., make requests, cast blame). In this entry, an abbreviated overview of the history of CA is provided, as well as a description of some of its core features.

History of CA

During the 1960s, CA was developed by a group of scholars in the United States who were working in the discipline of sociology. The field has multiple influences including ethnography, linguistic philosophy, and ethnomethodology. The early contributors to the development of CA include Harvey Sacks, Emanuel Schegloff, and Gail Jefferson. Sacks is credited as being the primary developer of the early and foundational ideas of CA, with his published *Lectures on Conversations* offering the early ideas that shaped CA.

In the 1960s, both Sacks and Schegloff studied with Erving Goffman at the University of California at Berkeley, where there was a particular emphasis on the value of observing people interacting with one another. This emphasis on examining face-to-face interactions deeply influenced the core assumptions of CA. Similarly, ethnomethodology and Harold Garfinkel's writing around the value of studying how people make sense and describe social facts shaped Sack's ideas as well. Beyond Garfinkel and Goffman, scholars such as Noam Chomsky, Ludwig Wittgenstein, and Sigmund Freud, among many others, are typically noted as having influenced the early ideas that led to the development of CA.

In his early work, Sacks was a fellow at the Center for the Scientific Study of Suicide at the University of California, Los Angeles, where he studied audio recordings of telephone calls made to a suicide prevention hotline. Sacks's work with these data ultimately shaped the core assumptions of CA, such as the idea that an interaction is a site of social action, and thus by studying interactions, the ordered nature of conversation can be revealed. Alongside Sacks, other scholars, such as Schegloff and Gail Jefferson, contributed to the early development of CA, which ultimately resulted in a turn to examining language use as a site wherein social order and norms were made visible and could be closely studied. Their collective work and ideas led to the development of analytical methods for describing the structured nature of social interaction. This included the development of a specialized transcription system, often referred to as the *Jefferson transcription system*, which focuses on representing both *what* people say and *how* they say it.

During the 1980s and 1990s, a great deal of CA scholarship highlighted the connections between talk

and social structural contexts. Since its early beginnings, CA has grown to be used and further developed in a range of disciplines including education, linguistics, and the health sciences, among others. In addition, a large body of CA scholarship is focused on the technical aspects of talk-in-interaction, with a sizable body of scholarship being focused on interactions in workplace settings. In the contemporary era, there is a growing focus on applying CA to applied contexts, such as health care settings or classrooms. Alongside this, there is a growing interest in considering how CA might be applied to digital forms of interactional data such as social media.

Core Features

The primary focus of CA is on the study of how talk is organized and the ways in which participants within a given interaction make sense of the interaction. Interactional patterns are identified through close study of the sequential organization of a given interaction. This kind of analysis focuses on conversational structures such as turn-taking and repair. As conversation analysts focus on talk as it is produced in a given interaction, they are analytically focused on what the talk is doing rather than simply on what the talk is about. In other words, there is a core assumption that talk produces social actions, as it is through talk that the work of social life is accomplished. Given this focus, it is common for conversation analysts to collect naturally occurring data, that is, data that exist independent of a researcher. This assumption is one that aligns with Sacks' early argument, that if a researcher desires to understand people's accounts and ways of making sense of the social world, they should examine their activities as they naturally happen. Hence, it is common for a CA study to focus on the collection of audio or video recordings of people going about their daily lives in an everyday or institutional context.

There are two distinct approaches to CA: basic CA and applied CA. Basic CA involves the analysis of everyday or mundane conversations, with a focus on examining the organization or structure of the talk. Applied CA, while typically drawing on the findings of basic CA research, focuses on studying talk within institutional settings and often poses research questions that emphasize the potential for application. Ultimately, CA allows researchers to study the micro (nuanced) components of talk, with particular emphasis on paying attention to detail (e.g., pauses, utterances, embodiment of speech). The focus on talk-in-interaction, and attention to nuance within specific speech acts, sets CA apart from other

methodological frameworks used within qualitative research.

COPULA FUNCTIONS

The word *copula* is a Latin noun that means a link and is used in grammar to describe the part of a proposition that connects the subject and predicate. Abe Sklar in 1959 was the first to introduce the word *copula* in a mathematical or statistical sense in a theorem describing the functions that join together one-dimensional distribution functions to form multivariate distribution functions. He called this class of functions *copulas*. In statistics, a copula is a function that links an n -dimensional cumulative distribution function to its one-dimensional margins and is itself a continuous distribution function characterizing the dependence structure of the model.

Recently, in multivariate modeling, much attention has been paid to copulas or *copula functions*. It can be shown that outside the elliptical world, correlation cannot be used to characterize the dependence between two series. To say it differently, the knowledge of two marginal distributions and the correlation does not determine the bivariate distribution of the underlying series. In this context, the only dependence function able to summarize all the information about the comovements of the two series is a copula function. Indeed, a multivariate distribution is fully and uniquely characterized by its marginal distributions and its dependence structure as represented by the copula.

Definition and Properties

In what follows, the definition of a copula is provided in the bivariate case.

A copula is a function $C : [0,1] \times [0,1] \rightarrow [0,1]$ with the following properties:

1. For every u, v in $[0,1]$, $C(u,0) = 0 = C(0,v)$, and $C(u,1) = u$ and $C(1,v) = v$.
2. For every u_1, u_2, v_1, v_2 in $[0,1]$, such that $v_1 \leq v_2$ and $u_1 \leq u_2$, $C(u_2, v_2) - C(u_2, v_1) - C(u_1, v_2) + C(u_1, v_1) \geq 0$.

An example is the product copula $C^+(u,v) = uv$, which is a very important copula because it characterizes independent random variables when the distribution functions are continuous.

One important property of copulas is the *Fréchet-Hoeffding bounds inequality*, given by

$$W(u,v) \leq C(u,v) \leq M(u,v),$$

where W and M are also copulas referred to as *Fréchet-Hoeffding* lower and upper bounds, respectively, and defined by $W(u,v) = \max(u+v-1, 0)$ and $M(u,v) = \min(u,v)$.

Much of the usefulness of copulas in nonparametric statistics is due to the fact that for strictly monotone transformations of the random variables under interest, copulas are either invariant or change in predictable ways. Specifically, let X and Y be continuous random variables with copula $C_{X,Y}$, and let f and g be strictly monotone functions on $\text{Ran } X$ and $\text{Ran } Y$ (Ran : Range), respectively.

1. If f and g are strictly increasing, then $C_{f(X),g(Y)}(u,v) = C_{X,Y}(u,v)$.
2. If f is strictly increasing and g is strictly decreasing, then $C_{f(X),g(Y)}(u,v) = u - C_{X,Y}(u, 1-v)$.
3. If f is strictly decreasing and g is strictly increasing, then $C_{f(X),g(Y)}(u,v) = v - C_{X,Y}(1-u, v)$.
4. If f and g are strictly decreasing, then $C_{f(X),g(Y)}(u,v) = u + v - 1 + C_{X,Y}(1-u, 1-v)$.

Sklar's Theorem for Continuous Distributions

Sklar's theorem defines the role that copulas play in the relationship between multivariate distribution functions and their univariate margins.

Sklar's Theorem in the Bivariate Case

Let H be a joint distribution function with continuous margins F and G . Then there exists a *unique* copula C such that for all $x, y \in \bar{R}$,

$$H(x, y) = C(F(x), G(y)) \quad (1)$$

Conversely, if C is a copula and F and G are distribution functions, then the function H defined by Equation 1 is a joint distribution function with margins F and G .

A multivariate version of this theorem exists and is presented hereafter.

Sklar's Theorem in n Dimensions

For any multivariate distribution function $F(x_1, x_2, \dots, x_n) = P(X_1 < x_1, X_2 < x_2, \dots, X_n < x_n)$ with continuous marginal functions $F_i(x_i) = P(X_i < x_i)$ for $1 < i < n$, there exists a unique function $C(u_1, u_2, \dots, u_n)$, called the copula and defined on $[0, 1]^n \cap [0, 1]$, such that for all $(x_1, x_2, \dots, x_n) \in R^n$,

$$F(x_1, x_2, \dots, x_n) = C(F_1(x_1), F_2(x_2), \dots, F_n(x_n)) \quad (2)$$

Conversely, if $C(u_1, u_2, \dots, u_n)$ is a copula and $F_i(x_i)$, $i = 1, 2, \dots, n$, are the distribution functions of n random variables X_i , then $F(x_1, x_2, \dots, x_n)$ defined above is an n -variate distribution function with margins $F_i, i = 1, 2, \dots, n$.

The expression of the copula function in Equation 2 is given in terms of cumulative distribution functions. If we further assume that each F_i and C is differentiable, the joint density $f(x_1, x_2, \dots, x_n)$ corresponding to the cumulative distribution $F(x_1, x_2, \dots, x_n)$ can easily be obtained using

$$f(x_1, x_2, \dots, x_n) = \frac{\partial^n F(x_1, x_2, \dots, x_n)}{\partial x_1 \partial x_2 \dots \partial x_n}.$$

This gives Equation 3:

$$f(x_1, x_2, \dots, x_n) = f_1(x_1) \times f_2(x_2) \times \dots \times f_n(x_n) \times c(u_1, u_2, \dots, u_n), \quad (3)$$

where the f_i s are the marginal densities corresponding to the F_i s, the u_i s are defined as $u_i = F_i(x_i)$, and $C(u_1, u_2, \dots, u_n)$ is the density of the copula C obtained as follows:

$$C(u_1, u_2, \dots, u_n) = \frac{\partial^n C(u_1, u_2, \dots, u_n)}{\partial u_1 \partial u_2 \dots \partial u_n}. \quad (4)$$

In contrast to the traditional modeling approach that decomposes the joint density as a product of marginal and conditional densities, Equation 3 states that, under appropriate conditions, the joint density can be written as a product of the marginal densities and the copula density. From Equation 3, it is clear that the density $c(u_1, u_2, \dots, u_n)$ encodes information about the dependence structure among the X_i s, and the f_i s describe the marginal behaviors. It thus shows that copulas represent a way to extract the

dependence structure from the joint distribution and to extricate the dependence and marginal behaviors. Hence, copula functions offer more flexibility in modeling multivariate random variables. This flexibility contrasts with the traditional use of the multivariate normal distribution, in which the margins are assumed to be Gaussian and linked through a linear correlation matrix.

Survival Copulas

A survival function $\bar{F}$ is defined as $\bar{F}(x) = P[X > x] = 1 - F(x)$, where F denotes the distribution function of X . For a pair (X, Y) of random variables with joint distribution function H , the joint survival function is given by $\bar{H}(x, y) = P[X > x, Y > y]$ with margins $\bar{F}$ and $\bar{G}$, which are the univariate survival functions. Let C be the copula of X and Y ; then

$$\begin{aligned}\bar{H}(x, y) &= 1 - F(x) - G(y) + H(x, y) \\ &= \bar{F}(x) + \bar{G}(y) - 1 + C(F(x), G(y)) \\ &= \bar{F}(x) + \bar{G}(y) - 1 + C(1 - \bar{F}(x), 1 - \bar{G}(y)).\end{aligned}$$

Let $\hat{C}$ be defined from $[0, 1] \times [0, 1]$ into $[0, 1]$ by $\hat{C}(u, v) = u + v - 1 + C(1 - u, 1 - v)$, then $\bar{H}(x, y) = \hat{C}(\bar{F}(x), \bar{G}(y))$.

Note that C links the joint survival function to its univariate margins in the same way a copula joins a bivariate cumulative function to its margins. Hence, $\hat{C}$ is a copula and is referred to as the survival copula of X and Y . Note also that the survival copula $\hat{C}$ is different from the joint survival function $\bar{C}$ for two uniform random variables whose joint distribution function is the copula C .

Simulation

Copulas can be used to generate a sample from a specified joint distribution. Such samples can then be used to study mathematical models of real-world systems or for statistical studies.

Various well-known procedures are used to generate independent uniform variates and to obtain samples from a given univariate distribution. More specifically, to obtain an observation x of a random variable X with distribution function F , use the following method, called the inverse distribution:

- Generate a uniform variate u
- Set $x = F^{-1}(u)$, where F^{-1} is any quasi-inverse of F .

By virtue of Sklar's theorem, we need only to generate a pair (u, v) of observations of uniform random

variables (U, V) whose distribution function is C , the copula of X and Y , and then transform those uniform variates via the inverse distribution function method. One procedure for generating such a pair (u, v) of uniform variates is the conditional distribution method. For this method, we need the conditional distribution function for V given $U = u$, denoted $C_u(v)$ and defined as follows:

$$\begin{aligned}C_u(v) &= P[V \leq v | U = u] \\ &= \lim_{\Delta u \rightarrow 0} \frac{C(u + \Delta u, v) - C(u, v)}{\Delta u} = \frac{\partial}{\partial u} C(u, v).\end{aligned}$$

The procedure described above becomes

- Generate two independent uniform variates u and t
- Set $v = C_u^{-1}(t)$, where C_u^{-1} is any quasi-inverse of C_u
- The desired pair is (u, v) .

Examples of Copulas

Several copula families are available that can incorporate the relationships between random variables. In what follows, the Gaussian copula and the Archimedean family of copulas are briefly discussed in a bivariate framework.

The Gaussian Copula

The Gaussian or normal copula can be obtained by inversion from the well-known Gaussian bivariate distribution. It is defined as follows:

$$C^{Ga}(u_1, u_2; \rho) = \Phi(\phi^{-1}(u_1), \Phi^{-1}(u_2); \rho),$$

where ϕ is the standard univariate Gaussian cumulative distribution and $\Phi(x, y; \rho)$ is the bivariate normal cumulative function with correlation ρ . Hence, the Gaussian or normal copula can be rewritten as follows:

$$\begin{aligned}C^{Ga}(u_1, u_2; \rho) &= \int_{-\infty}^{\phi^{-1}(u_1)} \int_{-\infty}^{\phi^{-1}(u_2)} \frac{1}{\sqrt{2\pi(1-\rho^2)}} \\ &\quad \exp\left\{-\frac{(s^2 - 2\rho st + t^2)}{2(1-\rho^2)}\right\} ds dt.\end{aligned}$$

Variables with standard normal marginal distributions and this dependence structure are standard bivariate normal variables with correlation coefficient ρ .

With $\rho = 0$ we obtain a very important special case of the Gaussian copula, which takes the form $C^\perp(u, v) = uv$ and is called product copula. The importance of this copula is related to the fact that two variables are independent if and only if their copula is the product copula.

The Archimedean Copulas

The Archimedean copulas are characterized by their generator ϕ through the following equation:

$$C(u_1, u_2) = \phi^{-1}(\phi(u_1) + \phi(u_2))$$

for $u_1, u_2 \in [0, 1]$.

The following table presents three parametric Archimedean families that have gained interest in biostatistics, actuarial science, and management science, namely, the *Clayton copula*, the *Gumbel copula*, and the *Frank copula*.

Family	$C(u_1, u_2)$	Generator $\phi(t)$	Comment
Clayton	$\max[(u_1^{-\theta} + u_2^{-\theta} - 1)^{-1/\theta}, 0]$	$\frac{1}{\theta}(t^{-\theta} - 1)$	$\theta > 0$
Gumbel	$\exp[-((- \ln(u_1))^\theta + (- \ln(u_2))^\theta)^{1/\theta}]$	$(-\ln(t))^\theta$	$\theta \geq 1$
Frank	$-\frac{1}{\theta} \ln \left[1 + \frac{(e^{-\theta u_1} - 1)(e^{-\theta u_2} - 1)}{(e^{-\theta} - 1)} \right]$	$-\ln \left[\frac{(e^{-\theta t} - 1)}{(e^{-\theta} - 1)} \right]$	$\theta > 0$

Each of the copulas presented in the preceding table is completely monotonic, and this allows for multivariate extension. If we assume that all pairs of random variables have the same ϕ and the same θ , the three copula functions can be extended by using the following relation:

$$C(u_1, u_2, \dots, u_n) = \phi^{-1}(-1)(\phi(u_1) + \phi(u_2) + \dots + \phi(u_n))$$

for $u_1, u_2 \in [0, 1]$.

Copulas and Dependence

Copulas are widely used in the study of dependence or association between random variables. Linear correlation (or Pearson's correlation) is the most frequently used measure of dependence in practice. Indeed, correlation is a natural measure of dependence in elliptical distributions (such as the multivariate normal and the multivariate t distribution). However, most random variables are not jointly elliptically distributed, and using linear correlation as a measure of dependence in such situations might prove misleading. Two important measures of dependence, known as *Kendall's tau* and *Spearman's rho*, provide perhaps the best alternatives to the linear correlation coefficient as measures of dependence for nonelliptical distributions and can be expressed in terms of the underlying copula. Before presenting these measures and how they are related to copulas, we need to define the concordance concept.

Concordance

Let (x_1, y_1) and (x_2, y_2) be two observations from a vector (X, Y) of continuous random variables. Then (x_1, y_1) and (x_2, y_2) are said to be concordant if $(x_1 - x_2)(y_1 - y_2) > 0$ and discordant if $(x_1 - x_2)(y_1 - y_2) < 0$.

Kendall's tau

Kendall's tau for a pair (X, Y) , distributed according to H , can be defined as the difference between the probabilities of concordance and discordance for two independent pairs (X_1, Y_1) and (X_2, Y_2) , each with distribution H . This gives

$$\tau_{X,Y} = \Pr\{(X_1 - X_2)(Y_1 - Y_2) > 0\} - \Pr\{(X_1 - X_2)(Y_1 - Y_2) < 0\}.$$

The probabilities of concordance and discordance can be evaluated by integrating over the distribution of (X_2, Y_2) .

In terms of copulas, Kendall's tau becomes

$$\tau_{X,Y} = 4 \int \int_{[0,1]^2} C(u, v) dC(u, v) - 1,$$

where C is the copula associated to (X, Y) .

Spearman's rho

Let (X_1, Y_1) , (X_2, Y_2) , and (X_3, Y_3) be three independent random vectors with a common joint distribution function H whose margins are F and G . Consider the vectors (X_1, Y_1) and (X_2, Y_3) —that is, a pair of vectors with the same margins, but one vector has distribution function H , while the components of the other are independent. The Spearman's rho coefficient associated to a pair (X, Y) , distributed according to H , is defined to be proportional to the probability of concordance minus the probability of discordance for the two vectors (X_1, Y_1) and (X_2, Y_3) :

$$\rho_{XY} = 3(\Pr\{(X_1 - X_2)(Y_1 - Y_3) > 0\} - \Pr\{(X_1 - X_2)(Y_1 - Y) < 0\}).$$

In terms of the copula C associated to the pair (X, Y) , Spearman's rho becomes

$$\begin{aligned} \rho_{X,Y} &= 12 \int \int_{[0,1]^2} uv dC(u, v) - 3 \\ &= 12 \int \int_{[0,1]^2} C(u, v) du dv - 3. \end{aligned}$$

Note that if we let $U = F(X)$ and $V = G(Y)$,

$$\begin{aligned} \rho_{X,Y} &= 12 \int \int_{[0,1]^2} uv dC(u, v) - 3 = 12E[UV] - 3 \\ &= \frac{E[UV] - 1/4}{1/12} = \frac{\text{Cov}(U, V)}{\sqrt{\text{Var}(U)}\sqrt{\text{Var}(V)}} \\ &= \text{Corr}(F(X), G(Y)) \end{aligned}$$

Kendall's tau and Spearman's rho are measures of dependence between two random variables. However,

to extend to higher dimensions, we simply write pairwise measures in an $n \times n$ matrix in the same way as is done for linear correlation.

CORE-PERIPHERY STRUCTURE

A core-periphery structure is a type of network structure in which core actors are densely interconnected, whereas periphery actors are sparsely interconnected and only connected to core actors. An ideal core-periphery structure consists of a core where actors are all linked with each other and a periphery where actors are only linked to those in the core but no one in the periphery. While the ideal core-periphery structure is very rare in practice, many social networks, as well as other complex networks, resemble a core-periphery structure to varying degrees, with a densely interconnected core surrounded by a sparse periphery. This entry discusses key features of the core-periphery structure, introduces popular methods for detecting such structures, and presents some examples.

The defining feature of a core-periphery structure is a partition of a network into two sets, a well-connected core and a sparsely connected periphery. There has been no consensus about the exact extent of the connections between the core and the periphery, however. Some scholars suggest a core actor should be

connected to all periphery actors, while others contend that it only needs to be connected to some periphery actors. The common ground is that core actors are expected to be reasonably well connected to periphery actors.

Usually only a relatively small number of actors are located in the core, but they play a prominent role in the overall network. Compared with periphery actors, they possess more power and enjoy more prestige due to their structural advantage. They are also more instrumental in diffusing information, innovations, and social norms. Dependency may emerge as periphery actors become dependent on the core for key resources embedded in the network.

Detecting Core-Periphery Structure

Core and periphery actors in a network play different roles. The detection of a core-periphery structure sheds light on both an actor's structural position and the functioning of the overall network. Scholars have developed a variety of quantitative methods to detect and measure a core-periphery structure.

The most well-known detection method is the *discrete approach*. It is based on the comparison of the observed network with the ideal core-periphery network that consists of a fully connected core and a periphery that has no internal connections. A network exhibits a core-periphery structure if its correlation with the ideal core-periphery network is high. This discrete approach is essentially a binary classification process that partitions all actors into two categories. A limitation of this approach is its oversimplification as it merely identifies two classes of actors. In the core, however, some actors may be more core-like than others; similarly, periphery actors are not all peripheral to the same degree. The discrete approach cannot reveal those nuances within each category.

Another popular method is built on the continuous approach in which each actor of the network is assigned a quantitative *coreness* score. Some algorithms have been proposed to calculate coreness scores. These scores are on a continuous spectrum. Actors with greater coreness scores are located closer to the core, whereas those with lower scores are positioned more toward the periphery. In doing so, the continuous approach is better at capturing nuanced variations in the core/periphery status among actors.

Examples

Core-periphery structures are commonly observed and experienced in our daily life. A typical scene in a social gathering is a few popular people in the center of social

interactions with many others on the margins. Marginal individuals may not know each other but know those well-connected individuals in the center.

Core-periphery structures have been found prevalent in a wide range of social networks including the circle of national elites, interlocking directorates, participants of collective action, co-authorship networks among scholars, scientific citation networks, and so on. Core-periphery structures play an important role in many social processes such as human migration and the diffusion of knowledge and innovations.

At the international level, world-system scholars portray the international community as a huge core-periphery structure containing a dense and cohesive core and a sparsely connected periphery, usually with a semiperiphery somewhere in between. The core is occupied by advanced industrialized countries, while the periphery is populated by less developed countries and the semiperiphery by industrializing or newly industrialized countries. The interactions in the international trade network reflect the typical pattern of a core-periphery structure. Core countries trade intensively with one another, and they also trade extensively with semiperipheral and peripheral countries. In contrast, peripheral countries are highly dependent on particular core countries in their foreign trade, and trade among peripheral countries is largely negligible. This core-periphery structure offers core countries structural advantages while giving rise to dependency of peripheral countries on core countries.

In addition, core-periphery structures have been detected in other complex systems such as the human brain, networks of immune and neuronal cells, protein structure networks, ecosystems, and animal networks. Engineered networks such as metropolitan transportation networks and the Internet also exhibit core-periphery structures in many occasions.

CORRECTION FOR ATTENUATION

Correction for attenuation (CA) is a method that allows researchers to estimate the relationship between two constructs as if they were measured perfectly reliably and free from random errors that occur in all observed measures. All research seeks to estimate the true relationship among constructs; because all measures of a construct contain random measurement error, the CA is especially important in order to estimate the relationships among constructs free from the effects of this error. It is called the CA because random measurement error attenuates, or makes smaller, the observed relationships between constructs. For correlations, the correction is as follows:

$$\rho_{xy} = \frac{r_{xy}}{\sqrt{r_{xx}}\sqrt{r_{yy}}}, \quad (1)$$

where δ_{xy} is the corrected correlation between variables x and y , r_{xy} is the observed correlation between variables x and y , r_{xx} is the reliability estimate for the x variable, and r_{yy} is the reliability estimate for the y variable. For standardized mean differences, the CA is as follows:

$$\delta_{xy} = \frac{d_{xy}}{\sqrt{r_{yy}}}, \quad (2)$$

where δ_{xy} is the corrected standardized mean difference, d_{xy} is the observed standardized mean difference, and r_{yy} is the reliability for the continuous variable. In both equations, the observed effect size (correlation or standardized mean difference) is placed in the numerator of the right half of the equation, and the square root of the reliability estimate(s) is (are) placed in the denominator of the right half of the equation. The outcome from the left half of the equation is the estimate of the relationship between perfectly reliable constructs. For example, using Equation 1, suppose the observed correlation between two variables is .25, the reliability for variable X is .70, and the reliability for variable Y is .80. The estimated true correlation between the two constructs is $.25 / (.70 \times .80) = .33$. This entry describes the properties and typical uses of CA,

shows how the CA equation is derived, and discusses advanced applications for CA.

Properties

Careful examination of both Equations 1 and 2 reveals some properties of the CA. One of these is that the lower the reliability estimate, the higher the corrected effect size. Suppose that in two research contexts, $r_{xy} = .20$ both times. In the first context, $r_{xx} = r_{yy} = .50$, and in the second context, $r_{xx} = r_{yy} = .75$. The first context, with the lower reliability estimates, yields a higher corrected correlation ($\rho_{xy} = .40$) than the second research context ($\rho_{xy} = .27$) with the higher reliability estimates. An extension of this property shows that there are diminishing returns for increases in reliability; increasing the reliability of the two measures raises the corrected effect size by smaller and smaller amounts, as highly reliable measures begin to approximate the construct level or “true” relationship, where constructs have perfect reliability. Suppose now that $\rho_{xy} = .30$. If $r_{xx} = r_{yy}$, the corrected correlations when the reliabilities equal .50, .60, .70, .80, and .90, then the corrected correlations are .60, .50, .43, .38, and .33, respectively. Notice that while the reliabilities increase by uniform amounts, the corrected correlation is altered less and less.

Another property of Equation 1 is that it is not necessary to have reliability estimates of both variables X and Y in order to employ the CA. When correcting for only one variable, such as in applied research (or when reliability estimates for one variable are not available), a value of 1.0 is substituted for the reliability estimate of the uncorrected variable.

Another important consideration is the accuracy of the reliability estimate. If the reliability estimate is too high, the CA will underestimate the “true” relationship between the variables. Similarly, if the reliability estimate is too low, the CA will overestimate this relationship. Also, because correlations are bounded ($-1.0 \leq r_{xy} \leq 1.0$), it is possible to overcorrect outside these bounds if one (or both) of the reliability estimates is too low.

Typical Uses

The CA has many applications in both basic and applied research. Because nearly every governing body in the social sciences advocates (if not requires) reporting effect sizes to indicate the strength of relationship, and because all effect sizes are attenuated because of measurement error, many experts recommend that researchers employ the CA when estimating the relationship between any pair of variables.

Basic research, at its essence, has a goal of estimating the true relationship between two constructs. The CA serves this end by estimating the relationship between measures that are free from measurement error, and all constructs are free from measurement error. In correlational research, the CA should be applied whenever two continuous variables are being related and when reliability estimates are available. However, when the reported effect size is either the d value or the point-biserial correlation, the categorical variable (e.g., gender or racial group membership) is typically assumed to be measured without error; as such, no correction is made for this variable, and the CA is applied only to the continuous variable. In experimental research, the experimental manipulation is also categorical in nature and is typically assumed to be recorded without random measurement error. Again, the CA is only applied to the continuous dependent variable.

Although applied research also has a goal of seeking an estimate of the relationship between two variables at its core, often there are additional considerations. For example, in applied academic or employment selection research, the goal is not to estimate the relationship between the predictor and criterion constructs but to estimate the relationship between the predictor *measure* and the criterion construct. As such, the CA is not applied to the predictor. To do so would estimate the relationship between a predictor measure and a perfectly reliable criterion. Similarly, instances in which the relationship of interest is between a predictor *measure* and a criterion *measure* (e.g., between Medical College Admission Test scores and medical board examinations), the CA would not be appropriate, as the relationship of interest is between two observed measures.

Derivation

In order to understand how and why the CA works, it is important to understand how the equation is derived. The derivation rests on two fundamental assumptions from classical test theory.

Assumption 1: An individual's observed score on a particular measure of a trait is made up of two components: the individual's true standing on that trait and random measurement error.

This first assumption is particularly important to the CA. It establishes the equation that has become nearly synonymous with classical test theory:

$$X = T + e, \quad (3)$$

where X is the observed score on a particular measure, T is the true standing of the individual on the construct underlying the measure, and e is random measurement error. Implicit in this equation is the fact that the construct in question is stable enough that there is a “true” score associated with it; if the construct being measured changes constantly, it is difficult to imagine a true score associated with that construct. As such, the CA is not appropriate when any of the constructs being measured are too unstable to be measured with a “true” score. Also revealed in this equation is that any departure from the true score in the observed score is entirely due to random measurement error.

Assumption 2: Error scores are completely random and do not correlate with true scores or other error scores.

This assumption provides the basis for how scores combine in composites. Because observed test scores are composites of true and error scores (see Assumption 1), Assumption 2 provides guidance on how these components combine when one is calculating the correlation between two composite variables. Suppose there are observed scores for two variables, A and B . Applying Equation 3,

$$X_a = T_a + e_a \quad (4)$$

$$X_b = T_b + e_b \quad (5)$$

where terms are defined as before, and subscripts denote which variable the terms came from. To calculate the correlation between two composite variables, it is easiest to use covariances. Assumption 2 defines how error terms in Equations 4 and 5 correlate with the other components

$$\text{Cov}(T_a, se_a) = \text{Cov}(T_b, se_b) = \text{Cov}(e_b, se_b) = 0, \quad (6)$$

where the $\text{Cov}()$ terms are the covariances among components in Equations 4 and 5. Suppose that one additional constraint is imposed: The observed score variance is 1.00. Applying Equations 3 and 6, this also means that the sum of true score variance and error score variance also equals 1.00. The covariance matrix between the components of variables A and B (from Equations 4, 5, and 6) is shown below:

$$\begin{bmatrix} \text{Var}(T_a) & 0 & \text{Cov}(T_a, T_b) & 0 \\ 0 & \text{Var}(e_a) & 0 & 0 \\ \text{Cov}(T_a, T_b) & 0 & \text{Var}(T_b) & 0 \\ 0 & 0 & 0 & \text{Var}(e_b) \end{bmatrix}, \quad (7)$$

where $\text{Cov}(T_a, T_b)$ is the covariance between true scores on variables A and B , and the $\text{Var}()$ terms are the

variances for the respective components defined earlier. The zero covariances between error scores and other variables are defined from Equation 6. It is known from statistical and psychometric theory that the correlation between two variables is equal to the covariance between the two variables divided by the square root of the variances of the two variables:

$$r_{ab} = \frac{\text{Cov}(A, B)}{\sqrt{\text{Var}_a} \sqrt{\text{Var}_b}}, \quad (8)$$

where Var_a and Var_b are variances for their respective variables. Borrowing notation defined in Equation 7 and substituting into Equation 8, the correlation between observed scores on variables A and B is

$$r_{ab} = \frac{\text{Cov}(T_a, T_b)}{\sqrt{[\text{Var}(T_a) + \text{Var}(e_a)]} \sqrt{[\text{Var}(T_b) + \text{Var}(e_b)]}}. \quad (9)$$

Since the observed scores have a variance of 1.00 (because of the condition imposed earlier) and because of Equation 6, the correlation between true scores is equal to the covariance between true scores [i.e., $\text{Cov}(T_a, T_b) = r_{ab}$]. Making this substitution into Equation 9:

$$r_{ab} = \frac{r_{ab}}{\sqrt{[\text{Var}(T_a) + \text{Var}(e_a)]} \sqrt{[\text{Var}(T_b) + \text{Var}(e_b)]}}, \quad (10)$$

where all terms are as defined earlier. Note that the same term, r_{ab} , appears on both sides of Equation 10. By definition, $r_{ab} = r_{ab}$; mathematically, Equation 10 can be true only if the denominator is equal to 1.0. Because it was defined earlier that the variance of observed scores equals 1.0, Equation 9 can hold true. This requirement is relaxed for Equation 11 with an additional substitution.

Suppose now that a measure was free from measurement error, as it would be at the construct level. At the construct level, true relationships among variables are being estimated. As such, Greek letters are used to denote these relationships. If the true relationship between variables A and B is to be estimated, Equation 10 becomes

$$\rho_{ab} = \frac{r_{ab}}{\sqrt{[\text{Var}(T_a) + \text{Var}(e_a)]} \sqrt{[\text{Var}(T_b) + \text{Var}(e_b)]}}, \quad (11)$$

where ρ_{ab} is the true correlation between variables A and B , as defined in Equation 1. Again, because variables are free from measurement error at the construct level (i.e., $\text{Var}(e_a) = \text{Var}(e_b) = 0$), Equation 11 becomes

$$\rho_{xy} = \frac{r_{xy}}{\sqrt{\text{Var}(T_x)} \sqrt{\text{Var}(T_y)}}. \quad (12)$$

Based on classical test theory, the reliability of a variable is defined to be the ratio of true score variance to observed score variance. In other words,

$$r_{xx} = \frac{Var(T)}{Var(X)}. \quad (13)$$

Because it was defined earlier that the observed score variance was equal to 1.0, Equation 13 can be rewritten to say that $r_{xx} = Var(T)$. Making this final substitution into Equation 12,

$$\rho_{ab} = \frac{r_{ab}}{\sqrt{r_{aa}}\sqrt{r_{bb}}}, \quad (14)$$

which is exactly equal to Equation 1 (save for the notation on variable names), or the CA. Though not provided here, a similar derivation can be used to obtain Equation 2, or the CA for d values.

Advanced Applications

There are some additional applications of the CA under relaxed assumptions. One of these primary applications is when the correlation between error terms is not assumed to be zero. The CA under this condition is as follows:

$$\rho_{xy} = \frac{r_{xy} - r_{e_x e_y} \sqrt{1 - r_{xx}} \sqrt{1 - r_{yy}}}{\sqrt{r_{xx}} \sqrt{r_{yy}}}, \quad (15)$$

where $r_{e_x e_y}$ is the correlation between error scores for variables X and Y , and the other terms are as defined earlier.

It is also possible to correct part (or semipartial correlations) and partial correlations for the influences of measurement error. Using the standard formula for the partial correlation (in true score metric) between variables X and Y , controlling for Z , we get

$$\rho_{xy \cdot z} = \frac{\rho_{xy} - \rho_{xz}\rho_{yz}}{\sqrt{1 - (\rho_{xz})^2} \sqrt{1 - (\rho_{yz})^2}}. \quad (16)$$

Substituting terms from Equation 1 into Equation 15 yields a formula to estimate the true partial correlation between variables X and Y , controlling for Z :

$$\rho_{xy \cdot z} = \frac{\frac{r_{xy}}{\sqrt{r_{xx}r_{yy}}} - \left(\frac{r_{xz}}{\sqrt{r_{xx}r_{zz}}} \right) \left(\frac{r_{yz}}{\sqrt{r_{yy}r_{zz}}} \right)}{\sqrt{1 - \left(\frac{r_{xz}}{\sqrt{r_{xx}r_{zz}}} \right)^2} \sqrt{1 - \left(\frac{r_{yz}}{\sqrt{r_{yy}r_{zz}}} \right)^2}}. \quad (17)$$

Finally, it is also possible to compute the partial correlation between variables X and Y , controlling for Z while allowing the error terms to correlate:

$$\rho_{xyz} = \frac{r_{zz}(r_{xy} - r_{e_x e_y} \sqrt{1 - r_{xx}} \sqrt{1 - r_{yy}}) - (r_{xz} - r_{e_x e_z} \sqrt{1 - r_{xx}} \sqrt{1 - r_{zz}})(r_{yz} - r_{e_y e_z} \sqrt{1 - r_{yy}} \sqrt{1 - r_{zz}})}{\sqrt{r_{xx}r_{zz}} - [r_{xz} - (r_{e_x e_z} \sqrt{1 - r_{xx}} \sqrt{1 - r_{zz}})]^2} \cdot \frac{1}{\sqrt{r_{yy}r_{zz}} - [r_{yz} - (r_{e_y e_z} \sqrt{1 - r_{yy}} \sqrt{1 - r_{zz}})]^2}. \quad (18)$$

Corrections for attenuation for part (or semipartial) correlations are also available under similar conditions as Equations 16 and 17.

CORRELATION

Correlation is a synonym for *association*. Within the framework of statistics, the term *correlation* refers to a group of indices that are employed to describe the magnitude and nature of a relationship between two or more variables. As a measure of correlation, which is commonly referred to as a *correlation coefficient*, is descriptive in nature, it cannot be employed to draw conclusions with regard to a cause–effect relationship between the variables in question. To infer cause and effect, it is necessary to conduct a controlled experiment involving an experimenter-manipulated independent variable in which subjects are randomly assigned to experimental conditions. Typically, data for which a

correlation coefficient is computed are also evaluated with regression analysis. The latter is a methodology for deriving an equation that can be employed to estimate or predict a subject's score on one variable from the subject's score on another variable. This entry discusses the history of correlation and measures for assessing correlation.

History

Although in actuality a number of other individuals had previously described the concept of correlation, Francis Galton, an English anthropologist, is generally credited with introducing the concept of correlation in a lecture on heredity he delivered in Great Britain in 1877. In 1896 Karl Pearson, an English statistician, further systematized Galton's ideas and introduced the now commonly employed product-moment correlation coefficient, which is represented by the symbol r , for interval-level or continuous data. In 1904 Charles Spearman, an English psychologist, published a method for computing a correlation for ranked data. During the 1900s numerous other individuals contributed to the theory and methodologies involved in correlation. Among the more notable contributors were William Gossett and Ronald Fisher, both of whom described the distribution of the r statistic; Udney Yule, who developed a correlational measure for categorical data, as well as working with Pearson to develop multiple correlation; Maurice Kendall, who developed alternative measures of correlation for ranked data; Harold Hotelling, who developed canonical correlation; and Sewall Wright, who developed path analysis.

The Pearson Product-Moment Correlation

The Pearson product-moment correlation is the most commonly encountered bivariate measure of correlation. A bivariate correlation assesses the degree of relationship between two variables. The product-moment correlation describes the degree to which a linear relationship (the linearity is assumed) exists between one variable designated as the *predictor variable* (represented symbolically by the letter X) and a second variable designated as the *criterion variable* (represented symbolically by the letter Y). The product-moment correlation is a measure of the degree to which the variables covary (i.e., vary in relation to one another). From a theoretical perspective, the product-moment correlation is the average of the products of the paired standard deviation scores of subjects on the two variables. The equation for computing the unbiased estimate of the population correlation is $r = (\sum z_x z_y) / (n - 1)$.

The value r computed for a sample correlation coefficient is employed as an estimate of ρ (the lowercase Greek letter rho), which represents the correlation between the two variables in the underlying population. The value of r will always fall within the range of -1 to $+1$ (i.e., $-1 \leq r \leq +1$). The absolute value of r (i.e., $|r|$) indicates the strength of the linear relationship between the two variables, with the strength of the relationship increasing as the absolute value of r approaches 1. When $r = \pm 1$, within the sample for which the correlation was computed, a subject's score on the criterion variable can be predicted perfectly from his or her score on the predictor variable. As the absolute value of r deviates from 1 and moves toward 0, the strength of the relationship between the variables decreases, such that when $r = 0$, prediction of a subject's score on the criterion variable from his or her score on the predictor variable will not be any more accurate than a prediction that is based purely on chance.

The sign of r indicates whether the linear relationship between the two variables is direct (i.e., an increase in one variable is associated with an increase in the other variable) or indirect (i.e., an increase in one variable is associated with a decrease on the other variable). The closer a positive value of r is to $+1$, the stronger (i.e., more consistent) the direct relationship between the variables, and the closer a negative value of r is to -1 , the stronger the indirect relationship between the two variables. If the relationship between the variables is best described by a curvilinear function, it is quite possible that the value computed for r will be close to zero. Because of the latter possibility, it is always recommended that a researcher construct a scatterplot of the data. A scatterplot is a graph that summarizes the two scores of each subject with a point in two-dimensional space. By examining the configuration of the scatterplot, a researcher can ascertain whether linear correlational analysis is best suited for evaluating the data.

Regression analysis is employed with the data to derive the equation of a *regression line* (also known as the *line of best fit*), which is the straight line that best describes the relationship between the two variables. To be more specific, a regression line is the straight line for which the sum of the squared vertical distances of all the points from the line is minimal. When $r = \pm 1$, all the points will fall on the regression line, and as the value of r moves toward zero, the vertical distances of the points from the line increase.

The general equation for a regression line is $Y' = a + bX$, where a = Y intercept, b = the slope of the line (with a positive correlation yielding a positively sloped line, and a negative correlation yielding a

negatively sloped line), X represents a given subject's score on the predictor variable, and Y' is the score on the criterion variable predicted for the subject.

An important part of regression analysis involves the analysis of residuals. A residual is the difference between the Y' value predicted for a subject and the subject's actual score on the criterion variable. Use of the regression equation for predictive purposes assumes that subjects for whom scores are being predicted are derived from the same population as the sample for which the regression equation was computed. Although numerous hypotheses can be evaluated within the framework of the product-moment correlation and regression analysis, the most common null hypothesis evaluated is that the underlying population correlation between the variables equals zero. It is important to note that in the case of a large sample size, computation of a correlation close to zero may result in rejection of the latter null hypothesis. In such a case, it is critical that a researcher distinguish between statistical significance and practical significance, in that it is possible that a statistically significant result derived for a small correlation will be of no practical value; in other words, it will have minimal predictive utility.

A value computed for a product-moment correlation will be reliable only if certain assumptions regarding the underlying population distribution have not been violated. Among the assumptions for the product-moment correlation are the following: (a) the distribution of the two variables is bivariate normal (i.e., each of the variables, as well as the linear combination of the variables, is distributed normally), (b) there is homoscedasticity (i.e., the strength of the relationship between the two variables is equal across the whole range of both variables), and (c) the residuals are independent.

Alternative Correlation Coefficients

A common criterion for determining which correlation should be employed for measuring the degree of association between two or more variables is the levels of measurement represented by the predictor and criterion variables. The product-moment correlation is appropriate to employ when both variables represent either interval-or ratio-level data. A special case of the product-moment correlation is the *point-biserial correlation*, which is employed when one of the variables represents interval or ratio data and the other variable is represented on a dichotomous nominal scale (e.g., two categories, such as male and female). When the original scale of measurement for both variables is interval or ratio but scores on one of the variables have been transformed into a dichotomous nominal scale, the *biserial correlation* is the appropriate measure to

compute. When the original scale of measurement for both variables is interval or ratio but scores on both of the variables have been transformed into a dichotomous nominal scale, the *tetrachoric correlation* is employed.

Multiple correlation involves a generalization of the product-moment correlation to evaluate the relationship between two or more predictor variables with a single criterion variable, with all the variables representing either interval or ratio data. Within the context of multiple correlation, partial and semipartial correlations can be computed. A *partial correlation* measures the relationship between two of the variables after any linear association one or more additional variables have with the two variables has been removed. A *semipartial correlation* measures the relationship between two of the variables after any linear association one or more additional variables have with one of the two variables has been removed. An extension of multiple correlation is *canonical correlation*, which involves assessing the relationship between a set of predictor variables (i.e., two or more) and a set of criterion variables.

A number of measures of association have been developed for evaluating data in which the scores of subjects have been rank ordered or the relationship between two or more variables is summarized in the format of a contingency table. Such measures may be employed when the data are presented in the latter formats or have been transformed from an interval or ratio format to one of the latter formats because one or more of the assumptions underlying the product-moment correlation are believed to have been saliently violated. Although, like the product-moment correlation, the range of values for some of the measures that will be noted is between -1 and $+1$, others may assume only a value between 0 and $+1$ or may be even more limited in range. Some alternative measures do not describe a linear relationship, and in some instances a statistic other than a correlation coefficient may be employed to express the degree of association between the variables.

Two methods of correlation that can be employed as measures of association when both variables are in the form of ordinal (i.e., rank order) data are *Spearman's rank order correlation* and *Kendall's tau*. *Kendall's coefficient of concordance* is a correlation that can be employed as a measure of association for evaluating three or more sets of ranks.

A number of measures of correlation or association are available for evaluating categorical data that are summarized in the format of a two-dimensional contingency table. The following measures can be computed when both the variables are dichotomous in nature: *phi coefficient* and *Yule's Q*. When both variables are

dichotomous or one or both of the variables have more than two categories, the following measures can be employed: *contingency coefficient*, *Cramer's phi*, and *odds ratio*.

The *intraclass correlation* and *Cohen's kappa* are measures of association that can be employed for assessing interjudge reliability (i.e., degree of agreement among judges), the former being employed when judgments are expressed in the form of interval or ratio data, and the latter when the data are summarized in the format of a contingency table.

Measures of *effect size*, which are employed within the context of an experiment to measure the degree of variability on a dependent variable that can be accounted for by the independent variable, represent another type of correlational measure. Representative of such measures are *omega squared* and *eta-squared*, both of which can be employed as measures of association for data evaluated with an analysis of variance.

In addition to all the aforementioned measures, more complex correlational methodologies are available for describing specific types of curvilinear relationships between two or more variables. Other correlational procedures, such as *path analysis* and *structural equation modeling*, are employed within the context of *causal modeling* (which employs correlation data to evaluate hypothesized causal relationships among variables).

CORRELATION COEFFICIENT

The correlation coefficient, or coefficient of correlation, typically denoted by the letter r , evaluates the similarity of two sets of measurements (i.e., two dependent variables) obtained from the same sample. To do so, the coefficient of correlation quantifies the amount of information, or shared variance, common to the two variables.

The idea of correlation is rather old, but the modern approach and definition of the coefficient of correlation was initiated by Francis Galton (in an evolutionary context) in the end of the 19th century and formalized by Karl Pearson in the early 20th century. The sampling distribution of this coefficient was mostly derived a few years later by Ronald Fisher, and this was the source of a lifelong enmity between these two giants of statistics.

The correlation coefficient takes values between -1 and $+1$ (inclusive). A value of $+1$ shows that the two series of measurements are measuring the same thing, whereas a value of -1 indicates that the two measurements are still measuring the same thing, but one measurement varies inversely to the other. A value of 0 indicates that the two series of measurements have nothing in common. It is important to note that the coefficient of correlation measures only the *linear* relationship between two variables and that its value is very sensitive to outliers.

The squared correlation gives the proportion of common variance between two variables and is also called the *coefficient of determination*. Subtracting the coefficient of determination from unity gives the proportion of variance not shared between two variables. This quantity is called the *coefficient of alienation*.

The significance of the coefficient of correlation can be tested with an F or a t test. This entry presents three different approaches that can be used to obtain p values: (1) the classical approach, which relies on Fisher's F distributions; (2) the Monte Carlo approach, which relies on computer simulations to derive empirical approximations of sampling distributions; and (3) the nonparametric permutation (also known as *randomization*) test, which evaluates the likelihood of the actual data against the set of all possible configurations of these data. In addition to p values, confidence intervals can be computed using Fisher's Z transform or the more modern, computationally based nonparametric Efron's bootstrap.

The coefficient of correlation always overestimates the intensity of the correlation in the population and needs to be *corrected* in order to provide a better estimation. The corrected value is called *shrunk* or *adjusted*. This entry also presents variations of the

correlation coefficients (often called *nonparametric measures of correlation*) that can be used with ordinal or nominal data.

Notations and Definition

Suppose we have S observations, and for each observation s , we have two measurements, denoted W_s and Y_s , with respective means denoted M_W and M_Y . For each observation, we define the cross-product as the product of the deviations of each variable from its mean. The sum of these cross-products, denoted SCP_{WY} , is computed as:

$$SCP_{WY} = \sum_s (W_s - M_W)(Y_s - M_Y). \quad (1)$$

The sum of the cross-products reflects the association between the variables. When the deviations have the same sign, they indicate a positive relationship, and when they have different signs, they indicate a negative relationship.

The average value of the SCP_{WY} is called the *covariance* (just like the variance, the covariance can be computed by dividing by S or by $S - 1$):

$$cov_{WY} = \frac{SCP}{\text{Number of observations}} = \frac{SCP}{S}. \quad (2)$$

The covariance reflects the association between the variables, but it is expressed in the original units of measurement. To eliminate the units, the covariance is normalized by division by the standard deviation of each variable. This defines the coefficient of correlation, denoted $r_{W,Y}$, which is equal to

$$r_{W,Y} = \frac{cov_{WY}}{\sigma_W \sigma_Y}, \quad (3)$$

where σ_W (respectively, σ_Y) denotes the standard deviation of W (respectively, Y), which is the square root of the variances computed as:

$$\sigma_W^2 = \frac{1}{S} \sum_s (W_s - M_W)^2 \quad \text{and} \quad (3a)$$

$$\sigma_Y^2 = \frac{1}{S} \sum_s (Y_s - M_Y)^2.$$

Rewriting Equation 3 gives a more practical formula:

$$r_{W,Y} = \frac{SCP_{WY}}{\sqrt{SS_W SS_Y}}, \quad (4)$$

where SCP is the sum of the cross-product, and SS_W and SS_Y are the sum of squares of W and Y , respectively.

Correlation Computation: An Example

The computation for the coefficient of correlation is illustrated with the following data, describing the values of W and Y for $S = 6$ subjects:

$$W_1 = 1, W_2 = 3, W_3 = 4, W_4 = 4, W_5 = 5, W_6 = 7$$

$$Y_1 = 16, Y_2 = 10, Y_3 = 12, Y_4 = 4, Y_5 = 8, Y_6 = 10.$$

Step 1

Compute the sum of the cross-products. First compute the means of W and Y :

$$M_W = \frac{1}{S} \sum_{s=1}^S W_s = \frac{24}{6} = 4 \quad \text{and}$$

$$M_Y = \frac{1}{S} \sum_{s=1}^S Y_s = \frac{60}{6} = 10.$$

The sum of the cross-products is then equal to

$$\begin{aligned} SCP_{WY} &= \sum_s (Y_s - M_Y)(W_s - M_W) \\ &= (16 - 10)(1 - 4) \\ &\quad + (10 - 10)(3 - 4) \\ &\quad + (12 - 10)(4 - 4) \\ &\quad + (4 - 10)(4 - 4) \\ &\quad + (8 - 10)(5 - 4) \\ &\quad + (10 - 10)(7 - 4) \\ &= (6 \times -3)(0 \times -1) \\ &\quad + (2 \times 0)(-6 \times 0) \\ &\quad + (-2 \times 1) + (0 \times 3) \\ &= -18 + 0 + 0 + 0 - 2 + 0 \\ &= -20. \end{aligned} \quad (5)$$

Step 2

Compute the sums of squares. The sum of squares of W_s is obtained as:

$$\begin{aligned} SS_W &= \sum_{s=1}^S (W_s - M_W)^2 \\ &= (1 - 4)^2 + (3 - 4)^2 + (4 - 4)^2 \\ &\quad + (4 - 4)^2 + (5 - 4)^2 + (7 - 4)^2 \\ &= (-3)^2 + (-1)^2 + 0^2 + 0^2 \\ &\quad + 1^2 + 3^2 \\ &= 9 + 1 + 0 + 0 + 1 + 9 \\ &= -18 + 0 + 0 + 0 - 2 + 0 \\ &= 20. \end{aligned} \quad (6)$$

The sum of squares of Y_s is

$$\begin{aligned}
 SS_Y &= \sum_{s=1}^5 (Y_s - M_Y)^2 \\
 &= (16 - 10)^2 + (10 - 10)^2 \\
 &\quad + (12 - 10)^2 + (4 - 10)^2 + (8 - 10)^2 \\
 &\quad + (10 - 10)^2 \\
 &= 6^2 + 0^2 + 2^2 + (-6)^2 + (-2)^2 + 0^2 \\
 &= 36 + 0 + 4 + 36 + 4 + 0 \\
 &= 80.
 \end{aligned} \tag{7}$$

Step 3

Compute $r_{W,Y}$. The coefficient of correlation between W and Y is equal to

$$\begin{aligned}
 r_{W,Y} &= \frac{\sum (Y_s - M_Y)(W_s - M_W)}{\sqrt{SS_Y \times SS_W}} = \frac{SCP_{WY}}{\sqrt{SS_W SS_Y}} \\
 &= \frac{-20}{\sqrt{80 \times 20}} = \frac{-20}{\sqrt{1600}} = -\frac{20}{40} \\
 &= -.5.
 \end{aligned} \tag{8}$$

This value of $r = .5$ can be interpreted as an indication of a negative linear relationship between W and Y —a conclusion confirmed by the visual examination of Figure 1.

Figure 1 The Scatter-Plot of Variables W and Y

Note: The plot shows that values of W and Y are negatively correlated because large values of one variable are paired with small value of the other variable and vice versa.

Properties of the Coefficient of Correlation

The coefficient of correlation is a number without unit. This occurs because dividing the units of the numerator by the same units in the denominator eliminates the units. Hence, the coefficient of correlation can be used to compare different studies performed using different variables.

The magnitude of the coefficient of correlation is always smaller than or equal to 1. This happens because the numerator of the coefficient of correlation (see Equation 4) is always smaller than or equal to its denominator (this property follows from the Cauchy-Schwartz inequality). A coefficient of correlation that is equal to +1 or 1 indicates that the plot of the observations will have all observations positioned on a line.

The squared coefficient of correlation gives the *proportion of common variance* between two variables. It is also called the *coefficient of determination*. In our example, the coefficient of determination is equal to $r_{WY}^2 = .25$. The proportion of variance not shared between the variables is called the *coefficient of alienation*, and for our example, it is equal to $1 - r_{WY}^2 = .75$.

Interpreting Correlation

The ubiquity of the coefficient of correlation in applied statistics and science is such that it is sometimes incorrectly interpreted. So it is worth stressing that (a) the coefficient of correlation measures only *linear*

Figure 2 A Perfect Nonlinear Relationship With a 0 Correlation ($r_{W,Y} = 0$)

relationships, (b) it is very sensitive to the effect of outliers (this is why the computation of a coefficient of correlation should always go with a graphical display of the relationship between the variables of interest), and (c) the correlation between two variables cannot be directly used to conclude that there is a *causal* relationship between these variables. These themes are developed in the following subsections.

Linear and Nonlinear Relationship

The coefficient of correlation measures only linear relationships between two variables and will miss nonlinear relationships. For example, Figure 2 displays a perfect nonlinear relationship between two variables (i.e., the data show a U-shaped relationship with Y being proportional to the square of W), but the coefficient of correlation is equal to 0.

Effect of Outliers

Observations far from the center of the distribution contribute a lot to the sum of the cross-products. In fact, as illustrated in Figure 3, a single extremely deviant observation (often called an *outlier*) can dramatically influence the value of r . Another famous example of the sensitivity of the coefficient of correlation to specific observations was provided, in 1973, by the statistician Francis Anscombe who created four very different bivariate distributions, all having a coefficient of correlation equal to .82.

Geometric Interpretation

Each set of observations can also be seen as a *vector* in an S dimensional space (one dimension per observation). Within this framework, the correlation is equal to the *cosine* of the angle between the two vectors after they have been centered by subtracting their respective mean. For example, a coefficient of correlation of $r = .50$ corresponds to a 150° angle. A coefficient of correlation of 0 corresponds to a right angle, and therefore two uncorrelated variables are called *orthogonal* (which is derived from the Greek word for right angle).

Correlation and Causation

The fact that two variables are correlated does not mean that one variable causes the other one: *Correlation is not causation*. For example, in France, the number of Catholic churches in a city, as well as the number of schools, is highly correlated with the number of cases of cirrhosis of the liver, the number of teenage pregnancies, and the number of violent deaths. Does this mean that churches and schools are sources of vice

and that newborns are murderers? Here, in fact, the observed correlation is due to a third variable, namely the size of the cities: the larger a city, the larger the number of churches, schools, alcoholics, and so forth. In this example, the correlation between number of churches or schools and alcoholics is called a *spurious* correlation because it reflects only their mutual correlation with a third variable (i.e., size of the city).

Testing the Significance of r

A null hypothesis test for r can be performed using an F statistic obtained as

$$F = \frac{r^2}{1-r^2} \times (S-2). \quad (9)$$

For our example, we find that

$$F = \frac{.25}{1-.25} \times (6-2) = \frac{.25}{.75} \times 4 = \frac{1}{3} \times 4 = \frac{4}{3} = 1.33.$$

To perform a statistical test, the next step is to evaluate the sampling distribution of the F -statistic. This

Figure 3 The Dangerous Effect of Outliers on the Value of the Coefficient of Correlation

Note: The correlation of the set of points represented by the circles is equal to $-.87$. When the point represented by the diamond is added to the set, the correlation is now equal to $+.61$ —a change that shows that a single outlier can determine the value of the coefficient of correlation.

Figure 4 The Fisher Distribution for $v_1 = 1$ and $v_2 = 4$, Along With $\alpha = .05$

Note: Critical value of $F = 7.7086$.

Figure 5 Histogram of Values of r^2 and F Computed From 1,000 Random Samples When the Null Hypothesis Is True

Note: The histograms show the *empirical* distribution of F and r^2 under the null hypothesis.

sampling distribution provides the probability of finding any given value of the F criterion (i.e., the p value) under the null hypothesis (i.e., when there is no correlation between the variables). If this p value is smaller than the chosen level (e.g., .05 or .01), then the null hypothesis can be rejected, and r is considered significant. The problem of finding the p value can be addressed in three ways: (1) the classical approach, which uses Fisher's F distributions; (2) the Monte Carlo approach, which generates empirical probability distributions; and (3) the (nonparametric) permutation test, which evaluates the likelihood of the actual configuration of results among all other possible configurations of results.

Classical Approach

To analytically derive the sampling distribution of F , several assumptions need to be made as follows: (a) the error of measurement is added to the true measure; (b) the error is independent of the measure; and (c) the mean error is normally distributed, has a mean of zero, and has a variance of σ_e^2 . When these assumptions hold and when the null hypothesis is true, the F statistic is distributed as a Fisher's F with $v_1 = 1$ and $v_2 = S - 2$ degrees of freedom. (Incidentally, an equivalent test can be performed using $t = \sqrt{F}$, which is distributed under H_0 as a Student's distribution with $v = S - 2$ degrees of freedom).

For our example, the Fisher distribution shown in Figure 4 has $v_1 = 1$ and $v_2 = S - 2 = 6 - 2 = 4$ and gives the sampling distribution of F . The use of this distribution will show that the probability of finding a value of $F = 1.33$ under H_0 is equal to $p \approx .313$ (most current statistical packages will routinely provide this value). Such a p value does not lead to rejecting H_0 at the usual levels of $\alpha = .05$ or $\alpha = .01$. An equivalent way of performing a test uses critical values that correspond to values of F whose p value is equal to a given α level. For our example, the critical value (found in tables available in most standard textbooks) for $\alpha = .05$ is equal to $F(1, 4) = 7.7086$. Any F with a value larger than the critical value leads to rejection of the null hypothesis at the chosen α level, whereas an F value smaller than the critical value leads one to fail to reject the null hypothesis. For our example, because $F = 1.33$ is smaller than the critical value of 7.7086, we cannot reject the null hypothesis.

Monte Carlo Approach

A modern alternative to the analytical derivation of the sampling distribution is to empirically obtain the sampling distribution of F when the null hypothesis is true. This approach is often called a *Monte Carlo approach*.

With the Monte Carlo approach, we generate a large number of random samples of observations (e.g., 1,000 or 10,000) and compute r and F for each sample. To generate these samples, we need to specify the shape of the population from which these samples are obtained. Let us use a normal distribution (this makes the assumptions for the Monte Carlo approach equivalent to the assumptions of the classical approach). The frequency distribution of these randomly generated samples provides an estimation of the sampling distribution of the statistic of interest (i.e., r or F). For our example, Figure 5 shows the histogram of the values of r^2 and F obtained for 1,000 random samples of six observations each. The horizontal axes represent

the different values of r^2 (top panel) and F (bottom panel) obtained for the 1,000 trials, and the vertical axis the number of occurrences of each value of r^2 and F . For example, the top panel shows that 160 samples (of the 1,000 trials) have a value of $r^2 = .01$, which was between 0 and .01 (this corresponds to the first bar of the histogram in Figure 5).

Figure 5 shows that the number of occurrences of a given value of r^2 and F decreases as an inverse function of their magnitude: The greater the value, the less likely it is to obtain it when there is no correlation in the population (i.e., when the null hypothesis is true). However, Figure 5 shows also that the probability of obtaining a large value of r^2 or F is not null. In other words, even when the null hypothesis is true, very large values of r^2 and F can be obtained.

From this point on, this entry focuses on the F distribution, but everything also applies to the r^2 distribution. After the sampling distribution has been obtained, the Monte Carlo procedure follows the same steps as the classical approach. Specifically, if the p value for the criterion is smaller than the chosen α level, the null hypothesis can be rejected. Equivalently, a value of F larger than the α -level critical value leads one to reject the null hypothesis for this α level.

For our example, we find that 310 random samples (of 1,000) had a value of F larger than $F = 1.33$, and this corresponds to a probability of $p = .310$ (compare with a value of $p = .313$ for the classical approach). Because this p value is not smaller than $\alpha = .05$, we cannot reject the null hypothesis. Using the critical value approach leads to the same decision. The empirical critical value for $\alpha = .05$ is equal to 7.55 (see Figure 5). Because the computed value of $F = 1.33$ is not larger than the critical value of 7.55, we do not reject the null hypothesis.

Permutation Tests

For both the Monte Carlo and the traditional (i.e., Fisher) approaches, we need to specify the shape of the distribution under the null hypothesis. The Monte Carlo approach can be used with any distribution (but we need to specify which one we want, but more of the time the normal distribution is chosen), and the classical approach assumes a normal distribution. An alternative way to look at a null hypothesis test is to evaluate whether the pattern of results for the experiment is a rare event by comparing it to all the other patterns of results that could have arisen from these data. This is called a *permutation* test or sometimes a *randomization* test.

This nonparametric approach originated with William Gosset (better known under his nom de plume

of *Student*) and Fisher who developed the (now standard) F approach because it was possible then to compute one F but very impractical to compute the F s for all possible permutations. If Student and Fisher could have had access to modern computers, it is likely that permutation tests would nowadays be the standard procedure.

So to perform a permutation test, we need to evaluate the probability of finding the value of the statistic of interest (e.g., r or F) that we have obtained, compared with all the values we could have obtained by permuting the values of the sample. For our example, we have six observations, and therefore there are

$$6! = 6 \times 5 \times 4 \times 3 \times 2 = 720$$

different possible patterns of results. Each of these patterns corresponds to a given permutation of the data. For instance, here is a possible permutation of the results for our example:

$$W_1 = 1; W_2 = 3; W_3 = 4; W_4 = 4; W_5 = 5; W_6 = 7,$$

$$Y_1 = 8; Y_2 = 10; Y_3 = 16; Y_4 = 12; Y_5 = 10; Y_6 = 4.$$

(Note that we need to permute just one of the two series of numbers; here, we permuted Y). This permutation gives a value of $r_{WY} = -.30$ and of $r_{WY}^2 = .09$. We computed the value of r_{WY}^2 for the remaining 718 permutations. The histogram is plotted in Figure 6, where for convenience, we have also plotted the histogram of the corresponding F values.

For our example, we want to use the permutation test to compute the probability associated with $r_{WY}^2 = .25$. This is obtained by computing the proportion of r_{WY}^2 larger than .25. We counted 220 r_{WY}^2 of 720 larger or equal to .25; this gives a probability of

$$p = \frac{220}{720} = .306.$$

It is interesting to note that this value is very close to the values found with the two other approaches (cf. Fisher distribution $p = .313$ and Monte Carlo $p = .310$). This similarity is confirmed by comparing Figure 6, where we have plotted the permutation histogram for F , with Figure 4, where we have plotted the Fisher distribution.

When the number of observations is small (as is the case for this example with six observations), it is possible to compute all the possible permutations. In this case, we have an *exact* permutation test. But the number of permutations grows very fast as the number of observations increases. For example, with 20 observations, the total

Figure 6 Histogram of F Values Computed From the $6! = 720$ Possible Permutations of the Six Scores of the Example

number of permutations is close to 2.4×10^{18} (this is a very big number). Such large numbers obviously prohibit computing all the permutations. Therefore, for samples of large size, we approximate the permutation test by using a large number (say 10,000 or 100,000) of random permutations (this approach is sometimes called a *Monte Carlo permutation test*).

Confidence Intervals

A null hypothesis test for a correlation coefficient computed on a (random) sample of observations obtained from a given population only evaluates if the population value of the correlation is zero, but this null hypothesis test informs neither about the *size* of the correlation in the population nor about the *expected size* of the correlation if the original study were to be replicated. These concerns are addressed by computing confidence intervals as they provide a *range* of likely values of the correlation in the population or for replications of the original studies. These intervals can be theoretically computed from analytical approaches (which, in general, require statistical assumptions such as normality of the scores in the population) or, more recently, by computational approaches such as the bootstrap (that require modern computation resources).

Classical Approach

The value of r computed from a sample is an estimation of the correlation of the population from which the sample was obtained. Suppose that we obtain a new sample from the same population and that we compute the value of the coefficient of correlation for this new sample. In what range is this value likely to fall? This question is answered by computing the confidence interval of the coefficient of correlation. This gives an upper bound and a lower bound between which the population coefficient of correlation is likely to stand. For example, we want to specify the range of values of $r_{w,y}$ in which the correlation in the population has a 95% chance of falling.

Using confidence intervals is more general than a null hypothesis test because if the confidence interval excludes the value 0, then we can reject the null hypothesis. But a confidence interval also gives a range of probable values for the correlation. Using confidence intervals has another big advantage: We can act as if we could accept the null hypothesis. To do so, we first compute the confidence interval of the coefficient of correlation and look at the largest magnitude it can have. If we consider that this value is small, then we can say that even if the magnitude of the population correlation is not zero, it is too small to be of interest. Conversely, we can give more weight to a conclusion if

we show that the smallest possible value for the coefficient of correlation will still be large enough to be impressive.

The problem of computing the confidence interval for r has been explored (once again) by Student and Fisher. Fisher found that the problem was not simple but that it could be simplified by transforming r into another variable called Z . This transformation, which is called Fisher's Z transform, creates a new Z variable whose sampling distribution is close to the normal distribution. Therefore, we can use the normal distribution to compute the confidence interval of Z , and this will give a lower and a higher bound for the population values of Z . Then we can transform these bounds back into r values (using the inverse Z transformation), and this gives a lower and upper bound for the possible values of r in the population.

Fisher's Z Transform

Fisher's Z transform is applied to a coefficient of correlation r according to the following formula:

$$Z = \frac{1}{2} [\ln(1+r) - \ln(1-r)], \quad (10)$$

where $\ln$ is the *natural* logarithm.

The inverse transformation, which gives r from Z , is obtained with the following formula:

$$r = \frac{\exp\{2 \times Z\} - 1}{\exp\{2 \times Z\} + 2}, \quad (11)$$

where $\exp\{x\}$ means to raise the number e to the power x (i.e., $\exp\{x\} = e^x$ and e is Euler's constant, which is approximately 2.71828). Most hand calculators can be used to compute both transformations.

Fisher showed that the new Z variable has a sampling distribution that is normal, with a mean of 0 and a variance of $S - 3$. From this distribution, we can compute directly the upper and lower bounds of Z and then transform them back into values of r .

Example

The computation of the confidence interval for the coefficient of correlation is illustrated using the previous example, in which we computed a coefficient of correlation of $r = .5$ on a sample made of $S = 6$ observations. The procedure can be decomposed into six steps, which are detailed next.

Step 1

Before doing any computation, we need to choose an α level that will correspond to the probability of finding the population value of r in the confidence

interval. Suppose we chose the value $\alpha = .05$. This means that we want to obtain a confidence interval such that there is a 95% chance, or $(1 - \alpha) = (1 - .05) = .95$, of having the population value being in the confidence interval that we will compute.

Step 2

Find in the table of the normal distribution the critical values corresponding to the chosen α level. Call this value Z_α . The most frequently used values are

$$\begin{aligned} Z_{\alpha=.10} &= 1.645 \quad (\alpha = .10) \\ Z_{\alpha=.05} &= 1.960 \quad (\alpha = .05) \\ Z_{\alpha=.01} &= 2.575 \quad (\alpha = .01) \\ Z_{\alpha=.001} &= 3.325 \quad (\alpha = .001). \end{aligned}$$

Step 3

Transform r into Z using Equation 10. For the present example, with $r = .50$, we find that $Z = .5493$.

Step 4

Compute a quantity called Q as:

$$Q = Z_\alpha \times \sqrt{\frac{1}{S-3}}.$$

For our example, we obtain

$$Q = Z_{.05} \times \sqrt{\frac{1}{6-3}} = 1.960 \times \sqrt{\frac{1}{3}} = 1.1316.$$

Step 5

Compute the lower and

$$\begin{aligned} \text{Lower limit} &= Z_{\text{lower}} = Z - Q \\ &= -0.5493 - 1.1316 = -1.6809, \\ \text{Upper limit} &= Z_{\text{upper}} = Z + Q \\ &= -0.5493 + 1.1316 = 0.5823. \end{aligned}$$

Step 6

Transform Z_{lower} and Z_{upper} into r_{lower} and r_{upper} . This is done with the use of Equation 11. For the present example, we find that

$$\begin{aligned} \text{Lower limit} &= r_{\text{lower}} = -.9330, \\ \text{Upper limit} &= r_{\text{upper}} = .5243. \end{aligned}$$

The range of possible values of r is very large: The value of the coefficient of correlation that we have computed could come from a population whose

Figure 7 Histogram of $r_{w,y}$ Values Computed From 1,000 Bootstrapped Samples Drawn With Replacement From the Data From Our Example

correlation could have been as low as $r_{\text{lower}} = -.9330$ or as high as $r_{\text{upper}} = .5243$. Also, because zero is in the range of possible values, we cannot reject the null hypothesis (which is also the conclusion reached with the null hypothesis tests).

It is worth noting that because the Z transformation is nonlinear, the confidence interval is *not* symmetric around r . Finally, current statistical practice recommends the routine use of confidence intervals because this approach is more informative than null hypothesis testing.

Efron's Bootstrap

A modern Monte Carlo approach for deriving confidence intervals was proposed by Bradley Efron. This approach, called the *bootstrap*, was probably the most important advance for inferential statistics in the second part of the 20th century.

The idea behind the bootstrap is simple but could be implemented only with modern computers, which explains why it is a recent development. With the bootstrap approach, we treat the sample as if it were the population of interest in order to estimate the sampling distribution of a statistic computed on the sample. Practically this means that to estimate the sampling distribution of a statistic, we just need to create bootstrap samples obtained by drawing observations with replacement (whereby each observation is put back into

the sample after it has been drawn) from the original sample. The distribution of the bootstrap samples is taken as the population distribution. Confidence intervals are then computed from the percentile of this distribution.

For our example, the first bootstrap sample that we obtained comprised the following observations (note that some observations are missing and some are repeated as a consequence of drawing with replacement):

- s_1 = observation 5,
- s_2 = observation 1,
- s_3 = observation 3,
- s_4 = observation 2,
- s_5 = observation 3,
- s_6 = observation 6.

This gives the following values for the first bootstrapped sample obtained by drawing with replacement from our example:

$$W_1 = 5; W_2 = 1; W_3 = 4; W_4 = 3; W_5 = 4; W_6 = 7,$$

$$Y_1 = 8; Y_2 = 16; Y_3 = 12; Y_4 = 10; Y_5 = 12; Y_6 = 10.$$

This bootstrapped sample gives a correlation of $r_{w,y} = -.73$.

If we repeat the bootstrap procedure for 1,000 samples, we obtain the sampling distribution of $r_{w,y}$

as shown in Figure 7. This figure shows that the values of $r_{w,y}$ vary a lot with such a small sample (in fact, these values cover the whole range of possible values from -1 to $+1$). In order to find the upper and the lower limits of a confidence interval, we look for the corresponding percentiles. For example, if we select a value of $\alpha = .05$, we look at the values of the bootstrapped distribution corresponding to the 2.5th and the 97.5th percentiles. In our example, we find that 2.5% of the values are smaller than $-.9487$ and that 2.5% of the values are larger than $.4093$. Therefore, these two values constitute the lower and the upper limits of the 95% confidence interval of the population estimation of $r_{w,y}$ (cf. the values obtained with Fisher's Z transform of $-.9330$ and $.5243$). Contrary to Fisher's Z transform approach, the bootstrap limits are not dependent on assumptions about the population or its parameters (but it is comforting to see that these two approaches concur for our example). Because the value of 0 is in the confidence interval of $r_{w,y}$, we cannot reject the null hypothesis. This shows once again that the confidence interval approach provides more information than the null hypothesis approach.

Shrunken and Adjusted r

The coefficient of correlation is a descriptive statistic that *always* overestimates the population correlation. This problem is similar to the problem of the estimation of the variance of a population from a sample. To obtain a better estimate of the population, the value r needs to be corrected. The corrected value of r (denoted here by $\tilde{r}^2$) goes under different names: corrected r , shrunken r , or adjusted r (there are some subtle differences between these different appellations, but we will ignore them here). Several correction formulas are available; the one most often used estimates the value of the population correlation as

$$\tilde{r}^2 = 1 - \left[(1 - r^2) \left(\frac{S-1}{S-2} \right) \right]. \quad (12)$$

For our example, this gives

$$\begin{aligned} \tilde{r}^2 &= 1 - \left[(1 - r^2) \left(\frac{S-1}{S-2} \right) \right] = 1 - \left[(1 - .25) \times \frac{5}{4} \right] \\ &= 1 - \left[.75 \times \frac{5}{4} \right] = 0.06. \end{aligned}$$

With this formula, we find that the estimation of the population correlation drops from $r = -.50$ to $\tilde{r}^2 = -\sqrt{\tilde{r}^2} = -\sqrt{.06} = -.24$.

Particular Cases of the Coefficient of Correlation

Mostly for historical reasons, some specific cases of the coefficient of correlation have their own names (in part because these special cases lead to simplified computational formulas). Specifically, when both variables are ranks (or transformed into ranks), we obtain the *Spearman rank correlation coefficient* (a related transformation will provide the *Kendall rank correlation coefficient*); when only one of the two variables is dichotomous and the other one we obtain the *point-biserial coefficient*; when both variables are dichotomous (i.e., they take only the values 0 and 1), we obtain the ϕ^2 (squared) *coefficient of correlation*; when both variables are nominal, we obtain the (squared coefficient) Cramer's V^2 coefficient also called ϕ' coefficient. The ϕ^2 , ϕ' , and V^2 coefficients are directly linked to the χ^2 statistic testing independence for a contingency table.

Spearman Rank Correlation Coefficients

The Spearman rank correlation coefficient, often denoted ρ , is obtained as the plain correlation coefficient computed on the rank ordered data (older texts often give a convenient computational formula now made obsolete by computers). As an illustration, with our previous example, the values of W and Y (reproduced here for convenience):

$$\begin{array}{cccccc} W_1 = 1 & W_2 = 3 & W_3 = 4 & W_4 = 4 & W_5 = 5 & W_6 = 7 \\ Y_1 = 16 & Y_2 = 10 & Y_3 = 12 & Y_4 = 4 & Y_5 = 8 & Y_6 = 10 \end{array}$$

are ranked as:

$$\begin{array}{cccccc} w_1 = 1.0 & w_2 = 2.0 & w_3 = 3.5 & w_4 = 3.5 & w_5 = 5.0 & w_6 = 6.0 \\ y_1 = 6.0 & y_2 = 3.5 & y_3 = 5.0 & y_4 = 1.0 & y_5 = 2.0 & y_6 = 3.5 \end{array}$$

Note that ties are assigned their average rank (so that the sum of the ranks is the same whether there are ties or not). Using Equation 4, the Spearman coefficient of correlation is obtained from the ranked values as

$$\begin{aligned} \rho_{wy} = r_{wy} &= \frac{SCP_{wy}}{\sqrt{SS_w \times SS_y}} = \frac{\sum (w_i - M_w)(y_i - M_y)}{\sqrt{\sum (w_i - M_w)^2 \sum (y_i - M_y)^2}} \\ &= \frac{-8.5}{\sqrt{17 \times 17}} = -.50. \end{aligned}$$

For this example, Pearson r and Spearman ρ give the same value; this is not in general the case, but they often give similar values. Spearman is, however, much less sensitive to extreme values.

Inferences for Spearman Coefficient of Correlation

For large number of observations (i.e., more than 10), the significance of ρ can be tested using Equation 9; for number of observations smaller than 10, exact tables of critical values can be found, for example, in Sidney Siegel's 1956 book *Nonparametric Statistics for the Behavioral Sciences*. For our example, these tables would indicate that in order to reach significance, the Spearman coefficient of correlation would need to have a magnitude larger than .829. With a value of $\rho = -.50$, our correlation fails to reach significance—a conclusion similar to the one obtained from the raw data.

Confidence intervals can be computed for Spearman using standard inferential procedures (i.e., Fisher's Z transform) or, better, combinatoric or bootstrapped based approaches (see Bishara & Hittner, 2017, for a recent review).

Kendall Rank Correlation Coefficients

By contrast with the Spearman correlation coefficient—which is just a variation over Pearson's correlation coefficient—the Kendall rank correlation coefficient (denoted τ) is nonmetric, based on combinatoric, and takes only into account the order between rankings. To do so, the ranks are broken into a set of ordered pairs and a distance (called the *symmetric difference distance*) is computed by counting the number of different pairs between the two rank orders. This difference is then scaled to fit the $[-1, 1]$ range of a coefficient of correlation. Because, Kendall's τ reflects the differences between rank orders it is sometimes called a *coefficient of disagreement* (see, e.g., Siegel, 1956).

So the first step is to express each variable as a set of ordered pairs of the observations. Here, if we keep the example used to illustrate Spearman correlation and name the observations from a to f , as shown in the following:

Observation	a	b	c
	$w_1 = 1.0$	$w_2 = 2.0$	$w_3 = 3.5$
	$y_1 = 6.0$	$y_2 = 3.5$	$y_3 = 5.0$
	d	e	f
	$w_4 = 3.5$	$w_5 = 5.0$	$w_6 = 6.0$
	$y_4 = 1.0$	$y_5 = 2.0$	$y_6 = 3.5$

we find that variable w is equivalent to the following set of pairs where the first element of the pair is strictly preferred to the second element (note that in a tie, the first element is *not* strictly preferred to the second one and so should not be listed):

$$\{(a,b),(a,c),(a,d),(a,e),(a,f),(b,c),(b,d),(b,e), \\ (b,f),(c,e),(c,f),(d,e),(d,f),(e,f)\}.$$

The same procedure gives the following set of pairs for variable y :

$$\{(b,a),(c,a),(d,a),(e,a),(f,a),(b,c),(d,b),(e,b), \\ (d,c),(e,c),(f,c),(d,e),(d,f),(e,f)\}.$$

The next step is to identify the pairs that differ between the two variables. Here, this set—denoted Δ —of mismatched pairs is equal to

$$\{(a,b),(a,c),(a,d),(a,e),(a,f),(b,d),(b,e),(b,f), \\ (c,e),(c,f),(b,a),(c,a),(d,a),(e,a),(f,a),(d,b), \\ (e,b),(f,b),(e,c),(f,c)\}.$$

The cardinal (i.e., number of elements here denoted d_Δ) of this set is called the *symmetric difference distance* between variables w and y : in this example, it is equal to $d_\Delta = 20$. Kendall's τ is then obtained by rescaling d_Δ to fit the $[-1, +1]$ interval of a correlation as

$$\tau = 1 - \frac{2d_\Delta}{S(S-1)}, \quad (13)$$

(where S is the number of observations). Here, we obtain

$$\tau = 1 - \frac{2d_\Delta}{S(S-1)} = 1 - \frac{2 \times 20}{6 \times 5} = 1 - \frac{4}{3} = -.3333.$$

Inferences for Kendall Coefficient of Correlation

For values of N smaller than 10, exact probabilities can be computed for τ and tables can be found (e.g., see Siegel, 1956, or Abdi, 2007). Such a table would indicate that for $S = 6$, τ would need to be at least as large as .7333 to be significant at the $\alpha = .05$ level. And so, with Kendall's τ (just like with the other coefficients), variables W and Y cannot be considered as significantly correlated.

For values of S larger than 10, τ is approximately distributed as a normal distribution with parameters

$$\mu_\tau = 0 \quad \text{and} \quad \sigma_\tau = \sqrt{\frac{2(2S+5)}{9S(S-1)}}. \quad (14)$$

And, therefore, a Z -statistic can easily be computed to test Kendall's τ for S larger than 10.

Cramer's V^2 and Phi

Test of independence for contingency tables is typically conducted by computing a χ^2 of independence. Like most tests, χ^2 can be rewritten as the product of two terms: the first term reflecting the intensity of the effect and the second term reflecting the number of

observations. In the case of χ^2 , this product can be expressed as:

$$\chi^2 = \phi^2 \times S \quad (15)$$

(ϕ^2 is also called the *Inertia* of the contingency table, especially in the context of multivariate approaches tailored for the analysis of contingency tables such as correspondence analysis, see, e.g., Abdi & Béra, 2018). Rewriting Equation 15 shows that

$$\phi^2 = \frac{\chi^2}{S}. \quad (16)$$

For an I by J contingency table, the coefficient ϕ^2 takes value between 0 and $\min(I, J) - 1$, it is therefore a squared coefficient of correlation for a 2×2 contingency table (note that, in this particular case, ϕ^2 would be equal to the squared Pearson correlation computed between two binary variables). In the general case, to obtain a squared correlation coefficient (i.e., taking values between 0 and 1), the coefficient ϕ^2 needs to be rescaled; doing so gives a squared correlation coefficient known as ϕ'^2 or Cramer V^2 computed as

$$\phi'^2 = V^2 = \frac{\phi^2}{\min(I-1, J-1)} = \frac{\chi^2}{S \times \min(I-1, J-1)}. \quad (17)$$

To illustrate the computation of these coefficients, consider the following 3×6 contingency table collecting the answers of 260 participants who were asked to associate one (and only one) color to the sound of a vowel:

	Yellow	Green	Orange	Blue	Red	Violet
ee	46	17	2	11	42	5
a	8	7	5	17	30	6
ou	1	2	15	14	16	16

The χ^2 of independence for this table is equal to $\chi^2 = 87.75$ with $2 \times 5 = 10$ degrees of freedom (with an associated p value smaller than .0001). The index ϕ^2 is then equal to $87.75/260 = .337$.

Inferences for these squared correlation coefficients are equivalent to inferences based on their χ^2 and so, in this example, these coefficients of correlation would be considered as significantly different from 0.

CORRESPONDENCE ANALYSIS

Correspondence analysis (CA) is a generalized principal component analysis (PCA) tailored for the analysis of qualitative data. Originally, CA was created to analyze contingency tables, but CA is so versatile that it is now used with a lot of other data table types that contain nonnegative numbers.

CA transforms a data table into two sets of *factor scores*: one set for the rows and one set for the columns. The factor scores give the best representation of the similarity structure of the rows and the columns of the original data table. In addition, the factors scores can be plotted as maps, which display the essential information of the original table. In these maps, rows and columns are displayed as points whose coordinates are the factor scores and where the dimensions are called *factors*. Interestingly, in CA, the factor scores of the rows and the columns have the same variance and, therefore, both rows and columns can be conveniently represented in one single map. The modern version of correspondence analysis and its geometric interpretation originated in France in the 1960s and is associated with the French school of *data analysis* (*analyse des données*).

As a technique, CA was often discovered (and then rediscovered) and so variations of correspondence analysis can be found under several names such as *dual-scaling*, *optimal scaling*, or *reciprocal averaging*. The multiple identities of correspondence analysis are a consequence of its versatility and large number of properties: It can be defined as the optimal solution for a lot of apparently different problems.

Notations

Matrices are denoted with upper case letters typeset in a boldface font, for example, $\mathbf{X}$ is a matrix. The elements of a matrix are denoted with a lower case italic font matching the matrix name with indices indicating the row and column positions of the element, for example, $x_{i,j}$ is the element located at the i th row and j th column of matrix $\mathbf{X}$. Vectors are denoted with lowercase letters typeset in a boldface font, for example, $\mathbf{c}$ is a vector. The elements of a vector are denoted with a lower case italic font matching the vector name with an index indicating the position of the element in the vector, for example, c_i is the i th element of $\mathbf{c}$. The superscript T applied to a matrix or vector indicates that this matrix or vector is transposed.

An Example: How French Writers Punctuate

This example comes from E. Brunet who analyzed the way punctuation marks were used by six French writers: Rousseau, Chateaubriand, Hugo, Zola, Proust, and Giraudoux. In his paper, Brunet gave a table recording the number of times each of these writers used three punctuation marks: the period, the comma, and all the other marks (i.e., interrogation mark, exclamation mark, colon, and semicolon) grouped together. These data are reproduced in Table 1. From these data, we can build the original data matrix, which is denoted

Table 1 The Punctuation Marks of Six French Writers

	<i>Period</i>	<i>Comma</i>	<i>All the other marks</i>
Rousseau	7,836	13,112	6,026
Chateaubriand	53,655	102,383	42,413
Hugo	115,615	184,541	59,226
Zola	161,926	340,479	62,754
Proust	38,177	105,101	12,670
Giraudoux	46,371	58,367	14,299

Source: From Brunet (1989).

$\mathbf{X}$. It has $I = 6$ rows and $J = 3$ columns and is equal to

$$\mathbf{X} = \begin{bmatrix} 7,836 & 13,112 & 6,026 \\ 53,655 & 102,383 & 42,413 \\ 115,615 & 184,541 & 59,226 \\ 161,926 & 340,479 & 62,754 \\ 38,177 & 105,101 & 12,670 \\ 46,371 & 58,367 & 14,299 \end{bmatrix}. \quad (1)$$

In the matrix $\mathbf{X}$, the rows represent the authors and the columns represent the types of punctuation marks. At the intersection of a row and a column, we find the number of a given punctuation mark (represented by the column) used by a given author (represented by the row).

Analyzing the rows

Suppose that the focus is on the *authors* and that we want to derive a map that reveals the similarities and differences in punctuation style between authors. In this map, the authors should be points and the distances between authors will reflect their stylistic proximity. So, on such a map, when two authors are close to each other, these two authors punctuate in a similar way, and when two authors are far away, these two authors punctuate differently.

A First (Bad) Idea: Doing PCA

A first idea is to perform a PCA on $\mathbf{X}$. The result is shown in Figure 1. The plot suggests that the data are quite unidimensional. And, in fact, the first component of this analysis explains 98% of the total inertia (a quantity akin to variance) of the data. How to interpret this component? It seems related to the *number* of punctuation marks produced by each author. This interpretation can be tested by creating a fictitious alias for Zola. To do so: Suppose that, unbeknown to most historians of French literature, Zola wrote a small novel under the (rather transparent) pseudonym of Alos. In this novel, he kept his usual way of punctuating, but because this is a short novel, he obviously produced a smaller number of punctuation marks than he did in his complete *œuvre*. Here is the (row) vector recording the number of occurrences of the punctuation marks for Alos:

$$[2,699 \quad 5,675 \quad 1,046]. \quad (2)$$

For ease of comparison, Zola's row vector is reproduced here:

$$[161,926 \quad 340,479 \quad 62,754]. \quad (3)$$

Figure 1 Principal Component Analysis of the Punctuation. Centered Data

Note: Alos is a supplementary element. Even though Alos punctuates the same way as Zola, Alos is further away from Zola than from any other author. The first dimension explains 98% of the variance. It reflects mainly the number of punctuation marks produced by the authors.

So, Alos and Zola have the same punctuation style and differ only in their prolixity. A good analysis should reveal such a similarity of style, but as Figure 1 shows, PCA fails. In this figure, we have projected Alos (as a supplementary element) in the analysis of the authors and Alos is, in fact, further away from Zola than from any other author. This example shows that using PCA to analyze the *style* of the authors is not a good idea because pca is mainly sensitive to the total *number* of punctuation marks produced rather than to *how* punctuation is used. But, the style of the authors, is, in fact, expressed by the *relative frequencies* of their use of the punctuation marks. This suggests that the data matrix should be transformed such that each author is described by the *proportion* of the usage of the punctuation marks rather than by the *number* of punctuation marks used. With this transformation, each row of the data matrix is now called a *row profile*: The entries of a row profile are all nonnegative and they sum to one. The transformed data matrix storing the row profiles is called (not surprisingly) a *row profile matrix*. In order to obtain the row profiles, we divide each row by its sum. The matrix of row profiles is denoted R . It is computed as:

$$R = \text{diag} X \mathbf{1}_{J \times 1}^{-1} X = \begin{bmatrix} .2905 & .4861 & .2234 \\ .2704 & .5159 & .2137 \\ .3217 & .5135 & .1648 \\ .2865 & .6024 & .1110 \\ .2448 & .6739 & .0812 \\ .3896 & .4903 & .1201 \end{bmatrix} \quad (4)$$

(where the diag operator transforms a vector into a diagonal matrix with the elements of this vector on the diagonal, and where $\mathbf{1}_{J \times 1}$ is a J by 1 vector of ones).

A convenient way to evaluate the differences between writers is to compare these writers to the *average writer*—a writer who would use each punctuation mark according to its proportion in the sample. The profile of this average writer is called the (row) *barycenter* (also called *centroid*, *center of mass*, or *center of gravity*) of the data matrix. Here, the barycenter of R is

a vector with $J = 3$ elements, it is denoted c and computed as:

$$c^T = \left(\underbrace{\mathbf{1}_{1 \times I} X \mathbf{1}_{J \times 1}}_{\text{Inverse of the total of } X} \right)^{-1} \times \underbrace{\mathbf{1}_{1 \times I} X}_{\text{Total of the columns of } X} \quad (5)$$

$$= [.2973 \quad .5642 \quad .1385].$$

If all authors punctuate the same way, they all punctuate like the average writer, and, therefore, in order to study the differences between authors, we need to analyze the matrix of *deviations* to the average writer. This matrix of deviations is denoted as Y and it is computed as:

$$Y = R - \left(\mathbf{1}_{I \times 1} \times c^T \right) = \begin{bmatrix} -.0068 & -.0781 & .0849 \\ -.0269 & -.0483 & .0752 \\ .0244 & -.0507 & .0263 \\ -.0107 & .0382 & -.0275 \\ -.0525 & .1097 & -.0573 \\ .0923 & -.0739 & -.0184 \end{bmatrix}. \quad (6)$$

Masses (Rows) and Weights (Columns)

In correspondence analysis, we assign a *mass* to each row and a weight to each column. The mass of each row reflects its importance in the sample. In other words, the mass of each row is the proportion of this row in the total of the table. The masses of the rows are stored in a vector denoted m , which is computed as:

$$m = \left(\underbrace{\mathbf{1}_{1 \times I} X \mathbf{1}_{J \times 1}}_{\text{Inverse of the total of } X} \right)^{-1} \times \underbrace{X \mathbf{1}_{J \times 1}}_{\text{Total of the rows of } X} \quad (7)$$

$$= [.0189 \quad .1393 \quad .2522 \quad .3966 \quad .1094 \quad .0835]^T.$$

From the vector m , we define the diagonal matrix of masses as $D_m = \text{diag} m$.

The weight of each column expresses its importance for *discriminating* between the authors. So, the weight of a column reflects the information this column provides to the identification of a given row. Here, the idea is that the information provided by a column is

inversely proportional to its frequency, which, itself, is equal to the value of this column component of the barycenter. Therefore, the column weights are computed as the inverse of the values of the barycenter. Specifically, if we denote by $\mathbf{w}$ the J by 1 weight vector for the columns, we have

$$\mathbf{w} = [w_j] = [c_j^{-1}]. \quad (8)$$

For our example, we obtain

$$\mathbf{w} = [w_j] = [c_j^{-1}] = \begin{bmatrix} 1 \\ 0.2973 \\ 1 \\ 0.5642 \\ 1 \\ 0.1385 \end{bmatrix} = \begin{bmatrix} 3.3641 \\ 1.7724 \\ 7.2190 \end{bmatrix}. \quad (9)$$

From vector $\mathbf{w}$, we define the matrix of column weights as:

$$\mathbf{D}_c^{-1} = \text{diag} \mathbf{w} = \text{diag} [c_j^{-1}] = \begin{bmatrix} 3.3641 & 0 & 0 \\ 0 & 1.7724 & 0 \\ 0 & 0 & 7.2190 \end{bmatrix}. \quad (10)$$

Generalized Singular Value Decomposition (GSVD) of $\mathbf{Y}$

With all these notations defined, correspondence analysis boils down to a gsvd problem. Specifically, matrix $\mathbf{Y}$ is decomposed using the GSVD under the constraints imposed by the matrices $\mathbf{D}_m$ (masses for the rows) and $\mathbf{D}_c^{-1}$ (weights for the columns):

$$\mathbf{Y} = \mathbf{P}\mathbf{A}\mathbf{Q}^T \quad \text{with:} \quad \mathbf{P}^T \mathbf{D}_m \mathbf{P} = \mathbf{Q}^T \mathbf{D}_c^{-1} \mathbf{Q} = \mathbf{I}, \quad (11)$$

where $\mathbf{P}$ is the matrix of the right singular vectors, $\mathbf{Q}$ is the matrix of the left singular vectors, and $\mathbf{A}$ is the diagonal matrix of the eigenvalues (in the GSVD framework, $\mathbf{D}_m$ and $\mathbf{D}_c^{-1}$ are also called *metric matrices* or simple *metrics*). From this, we get:

$$\mathbf{Y} = \underbrace{\begin{bmatrix} 1.7962 & 0.9919 \\ 1.4198 & 1.4340 \\ 0.7739 & -0.3978 \\ -0.6878 & 0.0223 \\ -1.6801 & 0.8450 \\ 0.3561 & -2.6275 \end{bmatrix}}_{\mathbf{P}} \times \underbrace{\begin{bmatrix} 0.1335 & 0 \\ 0 & 0.0747 \end{bmatrix}}_{\mathbf{A}} \times \underbrace{\begin{bmatrix} 0.1090 & -0.4114 & 0.3024 \\ -0.4439 & 0.2769 & 0.1670 \end{bmatrix}}_{\mathbf{Q}^T}. \quad (12)$$

Figure 2 Plot of the Correspondence Analysis of the Rows of Matrix $\mathbf{X}$

Note: The first two sets of factors of the analysis for the rows are plotted (i.e., this is the matrix $\mathbf{F}$). Each point represents an author. The variance of each set of factor scores is equal to its eigenvalue.

The rows of matrix $\mathbf{X}$ are now represented by their *factor scores* (which are the projections of the observations onto the singular vectors of $\mathbf{X}$). The row factor scores are stored in an $I = 3$ by $L = 2$ (L stands for the number of nonzero singular values) matrix denoted $\mathbf{F}$, which is obtained as

$$\mathbf{F} = \mathbf{P}\mathbf{A} = \begin{bmatrix} .2398 & .0741 \\ .1895 & .1071 \\ .1033 & -.0297 \\ -.0918 & .0017 \\ -.2243 & .0631 \\ .0475 & -.1963 \end{bmatrix}. \quad (13)$$

The variance of the factor scores for a given dimension is equal to the squared singular value of this dimension (note that the variance of the observations is computed taking into account their masses). Or, equivalently, we say that the variance of the factor scores of one dimension is equal to the eigenvalue of this dimension (i.e., the eigenvalue is the square of the singular value). This can be checked as follows:

$$\begin{aligned} \mathbf{F}^T \mathbf{D}_m \mathbf{F} &= \mathbf{A} \mathbf{P}^T \mathbf{D}_m \mathbf{P} \mathbf{A} = \mathbf{A}^2 = \mathbf{A} = \begin{bmatrix} .1335^2 & 0 \\ 0 & .0747^2 \end{bmatrix} \\ &= \begin{bmatrix} .0178 & 0 \\ 0 & .0056 \end{bmatrix}. \end{aligned} \quad (14)$$

We can display the results by plotting the factor scores as a map where each point represents a row of the matrix $\mathbf{X}$ (i.e., each point represents an author). This is done in Figure 2. On this map, the first dimension seems to be related to time (the rightmost authors are earlier authors, the leftmost authors are more recent), with the exception of Giraudoux who is a very recent author. The second dimension singularizes Giraudoux. These factors will be easier to understand after we have analyzed the columns. This can be done by analyzing the matrix $\mathbf{X}^T$. Equivalently this can be done by doing what is called the *dual analysis*.

Geometry of Correspondence Analysis

CA has a simple geometric interpretation. For example, when a row profile is interpreted as a vector, it can be represented as a point in a multidimensional space. This way, a row profile with values for J variables is represented as a point in a J -dimensional space but because the sum of a profile is equal to one, row profiles are, in fact points in a $(J-1)$ dimensional space. Also, because the components of a row profile take value in the interval $[0, 1]$, the points representing these row profiles can only lay in the subspace whose

extreme points have one component equal to one and all other components equal to zero. This subspace is called a *simplex*. For example, Figure 3 shows the two-dimensional simplex corresponding to the subspace of all possible row profiles with three components. As an illustration, the point describing Rousseau (with coordinates equal to $[\text{.2905 } .4861 \text{ } 2234]$) is also plotted. For this particular example, the simplex is an equilateral triangle and so the three dimensional row profiles can conveniently be represented as points on this triangle as illustrated in Figure 4a which shows the simplex of Figure 3 in two dimensions. Figure 4b shows all six authors and their barycenter.

The weights of the columns, which are used as constraints in the GSVD, have also a straightforward geometric interpretation. As illustrated in Figure 5, each side of the simplex is stretched by a quantity equal to the square root of the dimension it represents (we use the square root because we are interested in *squared* distances but not in squared weights, so using the square root of the weights ensures that the *squared* distances between authors will take into account the weights rather than the squared weights).

To find the factors, the masses of the rows are taken into account. Specifically, the first factor is computed

Figure 3 In Three Dimensions, the Simplex Is a Two-Dimensional Triangle Whose Vertices Are the Vectors $[100]$, $[010]$, and $[001]$

Note: The point describing Rousseau (with coordinates $[\text{.2905 } .4861 \text{ } 2234]$) is also plotted.

Figure 4 The Simplex as a Triangle

Note: (a) With Rousseau (compare with Figure 3), (b) with all six authors and their barycenter.

Figure 5 Geometric Interpretation of the Columns Weights

Note: Each side of the simplex is stretched by a factor equal to the square root of the weights.

such that it gives the maximum possible value of the sum of the masses times the squared projections of the authors points (i.e., the projections have the largest possible variance). The second factor is constrained to be orthogonal (taking into account the masses) to the first one and have the largest variance for the projections. The remaining factors are computed with similar constraints. Figure 6 shows the stretched simplex, the author points, and the two factors (note that the origin of the factors is the barycenter of the authors).

The “stretched simplex” shows the whole space of the possible profiles. Figure 6 shows that the authors occupy a small portion of the whole space—a pattern that reveals that the authors do not vary much in the way they punctuate. Also, the stretched simplex represents the columns as the vertices of the simplex: The columns are represented as row profiles with the column component being equal to one and all the other

components being equal to zero. This representation is called an *asymmetric* representation because the rows always have a dispersion smaller than (or equal to) the columns.

Distance, Inertia, Chi-square, and CA

Chi-squared distances

In CA, the Euclidean distance in the *stretched simplex* is equivalent to a weighted distance in the original space. For reasons—that will be clear later—this distance is called the χ^2 -distance. The χ^2 -distance between two row profiles i and i' can be computed from the factor scores as:

$$d_{i,i'}^2 = \sum_{\ell} (f_{i,\ell} - f_{i',\ell})^2 \quad (15)$$

Figure 6 Correspondence Analysis: The Stretched Simplex Along With the Factorial Axes

Note: The projections of the authors' points onto the factorial axes give the factor scores.

or from the row-profiles as

$$d_{i,i'}^2 = \sum_j w_j (r_{i,j} - r_{i',j})^2. \quad (16)$$

Inertia

The variability of the row profiles relative to their barycenter is measured by a quantity—akin to a variance—called *inertia* and denoted $\mathcal{I}$. The inertia of the rows to their barycenter is computed as the weighed sum of the squared distances of the rows to their barycenter. We denote by $d_{c,i}^2$ the (squared) distance of the i th row to the barycenter, it is computed as:

$$d_{c,i}^2 = \sum_j w_j (r_{i,j} - c_j)^2 = \sum_{\ell} f_{i,\ell}^2 \quad (17)$$

where L is the number of factors extracted by the CA of the table, this number is smaller or equal to $\min(I, J) - 1$. The inertia of the rows to their barycenter is then computed as:

$$\mathcal{I} = \sum_i m_i d_{c,i}^2. \quad (18)$$

The inertia can also be expressed as the sum of the eigenvalues (see Equation 14):

$$\mathcal{I} = \sum_{\ell} \lambda_{\ell}. \quad (19)$$

This shows that in CA, each factor extracts a portion of the inertia, with the first factor extracting the largest portion, the second factor extracting the largest portion left of the inertia, and so on.

Inertia and the Chi-square test

Interestingly, the inertia in CA is closely related to the *chi-square* test, which is traditionally performed on a contingency table in order to test the independence of the rows and the columns of the table. Under independence,

the frequency of each cell of the table should be proportional to the product of its row and column marginal probabilities. So, if we denote by $x_{+,+}$ the grand total of matrix $\mathbf{X}$, the expected frequency of the cell at the i th row and j th column is denoted $E_{i,j}$ and computed as:

$$E_{i,j} = m_i c_j x_{+,+}. \quad (20)$$

The *chi-square* test statistic, denoted χ^2 is computed as the sum of the squared difference between the actual values and the corresponding expected values weighted by the expected values:

$$\chi^2 = \sum_{i,j} \frac{(x_{i,j} - E_{i,j})^2}{E_{i,j}}. \quad (21)$$

When rows and columns are independent, χ^2 follows a *chi-square* distribution with $(I-1)(J-1)$ degrees of freedom. Therefore, χ^2 can be used to evaluate the likelihood of the row and columns independence hypothesis. The statistics χ^2 can be rewritten to show its close relationship with the inertia of CA, namely:

$$\chi^2 = \mathcal{I} \times x_{+,+} = \varphi^2 \times x_{+,+}, \quad (22)$$

with $\varphi^2 = \mathcal{I}$ being the coefficient of effect size associated to χ^2 (this index takes values between 0 and $\min(I, J) - 1$). Equation 22 shows that CA decomposes—in orthogonal components—the pattern of deviations to independence.

Dual Analysis: the Column Space

In a contingency table, the rows and the columns of the table play a similar role, and therefore, the analysis that was performed on the rows can also be performed on the columns by exchanging the role of the rows and the columns. This is illustrated by the analysis of the columns of matrix $\mathbf{X}$ or equivalently by the rows of the transposed matrix $\mathbf{X}^T$. The matrix of column profiles for $\mathbf{X}^T$ is called $\mathbf{O}$ (like cOlmun) and is computed as:

$$\mathbf{O} = \text{diag} \mathbf{X}^T \mathbf{1}_{l \times 1}^{-1} \mathbf{X}^T. \quad (23)$$

The matrix of the column deviations to their bary-center is called $\mathbf{Z}$ and it is computed as:

$$\mathbf{Z} = \mathbf{O} - \left(\mathbf{1}_{l \times 1} \times \mathbf{m}^T \right) \quad (24)$$

$$= \begin{bmatrix} -0.0004 & -0.0126 & .0207 & -0.0143 & -0.0193 & .0259 \\ -0.0026 & -0.0119 & -0.0227 & .0269 & .0213 & -0.0109 \\ .0116 & .0756 & .0478 & -0.0787 & -0.0453 & -0.0111 \end{bmatrix}.$$

Weights and masses of the column analysis are the inverse of their equivalent for the row analysis. This implies that the punctuation marks factor scores are obtained from the GSVD with the constraints imposed by the two metric matrices $\mathbf{D}_c$ (masses for the columns) and $\mathbf{D}_m^{-1}$ (weights for the rows, compare with Equation 11):

$$\mathbf{Z} = \mathbf{U} \mathbf{\Delta} \mathbf{V}^T \quad \text{with:} \quad \mathbf{U}^T \mathbf{D}_c \mathbf{U} = \mathbf{V}^T \mathbf{D}_m^{-1} \mathbf{V} = \mathbf{I}. \quad (25)$$

This gives

$$\mathbf{Z} = \underbrace{\begin{bmatrix} 0.3666 & -1.4932 \\ -0.7291 & 0.4907 \\ 2.1830 & 1.2056 \end{bmatrix}}_{\mathbf{U}} \times \underbrace{\begin{bmatrix} 0.1335 & 0 \\ 0 & 0.0747 \end{bmatrix}}_{\mathbf{\Delta}} \quad (26)$$

$$\times \underbrace{\begin{bmatrix} 0.0340 & 0.1977 & 0.1952 & -0.2728 & -0.1839 & 0.0298 \\ 0.0188 & 0.1997 & -0.1003 & 0.0089 & 0.0925 & -0.2195 \end{bmatrix}}_{\mathbf{V}^T}.$$

The factor scores for the punctuation marks are stored in a $J = 3 \times L = 2$ matrix denoted $\mathbf{G}$, which is computed in the same way $\mathbf{F}$ was computed (see Equation 13). Specifically, $\mathbf{G}$ is computed as:

$$\mathbf{G} = \mathbf{U} \mathbf{\Delta} = \begin{bmatrix} .0489 & -.1115 \\ -.0973 & .0367 \\ .2914 & .0901 \end{bmatrix}. \quad (27)$$

Transition Formula: From the Rows to the Columns and Back

A comparison of Equation 26 and Equation 12 shows that the singular values are the same for both the row and the column analyses. This means that the inertia extracted by each factor (i.e., the eigenvalue associated to this factor, which is also the square of the singular value) is the same for both analyses. Because the variance extracted by the factors can be added, to obtain the total inertia of the data table, this also means that each analysis is decomposing the same inertia that, here, is equal to

$$\mathcal{I} = .1335^2 + .747^2 = .0178 + .0056 = 0.0234. \quad (28)$$

Also, the generalized singular decomposition of one set (say the columns) can be obtained from the other one (say the rows). For example, the generalized singular vectors of the analysis of the columns can be computed directly from the analysis from the rows as

$$\mathbf{U} = \mathbf{D}_c^{-1} \mathbf{Q}. \quad (29)$$

Combining Equations 29 and 27 shows that the factors for the rows of $\mathbf{Z}$ (i.e., the punctuation marks) can be obtained directly from the singular value decomposition of the authors matrix (i.e., matrix $\mathbf{Y}$) as

$$\mathbf{G} = \mathbf{U} \mathbf{\Delta} = \mathbf{D}_c^{-1} \mathbf{Q} \mathbf{\Delta} \quad (30)$$

As a consequence, we can, in fact, find directly the factor scores of the columns from their profile matrix (i.e., the matrix $\mathbf{O}$) and from the factor scores of the rows. Specifically, the equation that gives the values of $\mathbf{G}$ from $\mathbf{F}$ is

$$\mathbf{G} = \mathbf{O} \mathbf{F} \mathbf{\Delta}^{-1}, \quad (31)$$

and conversely $\mathbf{F}$ could be obtained from $\mathbf{G}$ as

$$\mathbf{F} = \mathbf{R} \mathbf{G} \mathbf{\Delta}^{-1} \quad (32)$$

These equations are called *transition formulas from the rows to the columns* (and vice versa) or simply the *transition formulas*.

One single GSVD for CA

Because the factor scores obtained for the rows and the columns have the same variance (i.e., they have the same *scale*), it is possible to plot them in the same space.

Figure 7 Correspondence Analysis of Six Authors (Rousseau, Chateaubriand, Hugo, Zola, Proust, and Giraudoux) Described by the Way They Used Three Punctuation Marks (Comma, Period, and Others)

This is illustrated in Figure 7. The symmetry of the rows and the columns in CA is revealed by the possibility of directly obtaining the factors scores from one single GSVD. Specifically, let $\mathbf{N}$ denote the matrix $\mathbf{X}$ divided by the sum of all its elements. This matrix—sometimes called a *correspondence matrix*—has all elements larger than zero and their sum equal to one. The factors scores for the rows and the columns are obtained from the following GSVD:

$$(\mathbf{N} - \mathbf{mc}^T) = \mathbf{S}\mathbf{\Delta}\mathbf{T}^T \quad \text{with} \quad \mathbf{S}^T\mathbf{D}_m^{-1}\mathbf{S} = \mathbf{T}^T\mathbf{D}_c^{-1}\mathbf{T} = \mathbf{I}. \quad (33)$$

With the decomposition from Equation 33, the factor scores for the rows ($\mathbf{F}$) and the columns ($\mathbf{G}$) are obtained respectively as

$$\mathbf{F} = \mathbf{D}_m^{-1}\mathbf{S}\mathbf{\Delta} \quad \text{and} \quad \mathbf{G} = \mathbf{D}_c^{-1}\mathbf{T}\mathbf{\Delta} \quad (34)$$

Supplementary Elements

Often in CA, we want to know the position in the analysis of rows or columns that were not analyzed.

These rows or columns are called *illustrative* or *supplementary rows* or *columns* (or *supplementary observations* or *variables*). The appellation *out of sample* observations or variables is also sometimes used. By contrast, with these supplementary elements (which are *not* used to compute the factors), the *active* elements are those used to compute the factors. Table 2 shows the punctuation data table with four additional columns giving the detail of the “other punctuation marks” (i.e., the exclamation mark, the interrogation mark, the semicolon, and the colon). These punctuation marks were not analyzed for two reasons: first, these marks are too rare and therefore they would distort the factor space and, second, the *Other* marks comprises all these other marks and therefore to analyze them with *Other* would be redundant. There is also a new author in Table 2: We counted the marks used by a different author, namely Hervé Abdi in the first chapter of his 1994 book called *Les réseaux de neurones*. This author was not analyzed here because data are available for only one chapter (not his complete work) and also because this author (despite all his stylistic qualities) is not, strictly speaking, a literary author.

Table 2 Number of Punctuation Marks Used by Six Major French Authors

	Active Elements			x_{+j}	m $\frac{x_{i+}}{x_{++}}$	Supplementary Elements			
	Period	Comma	Other Marks			Exclamation	Question	Semicolon	Colon
Rousseau	7,836	1,3112	6,026	26,974	.0189	413	1,240	3,401	972
Chateaubriand	53,655	1,02383	4,2413	198,451	.1393	4,669	4,595	19,354	13,795
Hugo	115,615	1,84541	59,226	359,382	.2522	19,513	9,876	22,585	7,252
Zola	161,926	3,40479	62,754	565,159	.3966	24,025	10,665	18,391	9,673
Proust	38,117	1,05101	12,670	155,948	.1094	2,756	2,448	3,850	3,616
Giraudoux	46,371	5,8367	14,229	119,037	.0835	5,893	5,042	1,946	1,418
x_{+j}	423,580	8,03983	197,388	1424,951					
$\mathbf{w}^T = \frac{x_{++}}{x_{+j}}$	3.3641	1.7724	7.2190	x_{++}					
$\mathbf{c}^T = \frac{x_{+j}}{x_{++}}$	.2973	.5642	.1385						
Abdi (Chapter 1)	216	139	26						

Note: Notations x_{i+} = sum of the i th row; x_{+j} = sum of the j th column; x_{++} = grand total. The exclamation point, question mark, semicolon, and colon are supplementary columns. Abdi (1994), Chapter 1, is a supplementary row.

Source: From Brunet (1989).

The values of the projections on the factors for the supplementary elements are computed from the *transition formula*. Specifically, a supplementary row is projected into the space defined using the transition formula for the active rows (cf. Equation 31) and replacing the active row profiles by the supplementary row profiles. So, if we denote by $\mathbf{R}_{\text{sup}}$ the matrix of the supplementary row profiles, then $\mathbf{F}_{\text{sup}}$ —the matrix of the supplementary row factor scores—is computed as:

$$\mathbf{F}_{\text{sup}} = \mathbf{R}_{\text{sup}} \times \mathbf{G} \times \Delta^{-1}. \quad (35)$$

Table 3 lists the factor scores for the active and supplementary rows. For example, the factor scores of the author Abdi are computed as

$$\mathbf{F}_{\text{sup}} = \mathbf{R}_{\text{sup}} \mathbf{G} \Delta^{-1} = \begin{bmatrix} 0.0908 & -0.5852 \end{bmatrix}. \quad (36)$$

Supplementary columns are projected into the factor space using the transition formula from the active rows (cf. Equation 31) and replacing the active column profiles by the supplementary column profiles. So, if we denote by $\mathbf{O}_{\text{sup}}$ the supplementary column profile matrix, then $\mathbf{G}_{\text{sup}}$, the matrix of the supplementary column factor scores, is computed as

$$\mathbf{G}_{\text{sup}} = \mathbf{O}_{\text{sup}} \mathbf{F} \Delta^{-1}. \quad (37)$$

Table 4 lists the factor scores for the active and supplementary elements, and Figure 8 displays the supplementary columns (i.e., the *Other* punctuation marks) and the supplementary author (Abdi).

Figure 8 reveals that the *Other* punctuation mark category comprises two distinct groups: (1) the first group includes *Colon* and *Semicolon*, which are punctuation marks used more than average by the early authors; whereas (2) the second group includes *interrogation* and *exclamation* marks, which are punctuation marks used more than average by Giraudoux (who as writer of plays frequently uses spoken dialogues rich in *interrogation* and *exclamation* marks). Note that because the four supplementary punctuation marks add up to the *Other* punctuation mark, the *Other* mark is the barycenter of the four *Other* marks.

For the supplementary author, Abdi—whose linguistic corpus originates from scientific writing—is plotted far from the origin on the negative side of Dimension 2 because he wrote short sentences (a hallmark of scientific writing) and therefore used more periods and fewer commas and other punctuation marks than the average writer.

Little Helpers: Contributions and Cosines

Contributions and cosines are coefficients whose goal is to facilitate the interpretation. The contributions identify the important elements for a given factor, whereas the (squared) cosines identify the factors important for a given element. These coefficients express importance as the proportion of something into a total. The contribution is the ratio of the weighted squared projection of an element on a factor to the sum

Table 3 Factor Scores, Contributions, and Cosines for the Rows

Axis	λ	%	Rousseau	Chateaubriand	Hugo	Zola	Proust	Giraudoux	Abdi (Chapter 1)
Factor scores									
1	0.0178	76	0.2398	0.1895	0.1033	-0.0918	-0.2243	0.0475	-0.0908

Squared distances to grand barycenter									
—	—		0.0148	0.0108	0.0930	0.0573	0.0830	0.3090	0.3853

Note: Negative contributions are shown in *italic*. Exclamation mark, question mark, semicolon, and colon are supplementary columns.

**Figure 8** Correspondence Analysis of the Punctuation of Six Authors

Note: Comma, period, and others are active columns; Rousseau, Chateaubriand, Hugo, Zola, Proust, and Giraudoux are active rows; colon, semicolon, interrogation, and exclamation are supplementary columns; Abdi is a supplementary row.

of the weighted projections of all the elements for this factor (which happens to be the eigenvalue of this factor). The squared cosine is the ratio of the squared projection of an element onto a factor to the sum of the projections of this element on all the factors (which happens to be the squared distance from this point to the barycenter). Contributions and squared cosines, being proportions, take values between 0 and 1.

The squared *cosines*, denoted h , between row i and factor ℓ (respectively, between column j and factor ℓ) are obtained as:

$$h_{i,\ell} = \frac{f_{i,\ell}^2}{\sum_{\ell} f_{i,\ell}^2} = \frac{f_{i,\ell}^2}{d_{c,i}^2} \quad \text{and} \quad h_{j,\ell} = \frac{g_{j,\ell}^2}{\sum_{\ell} g_{j,\ell}^2} = \frac{g_{j,\ell}^2}{d_{r,j}^2}. \quad (38)$$

Squared cosines help locate the factors important for a given observation. The *contributions*, denoted b , of row i to factor ℓ and of column j to factor ℓ are obtained respectively as:

$$b_{i,\ell} = \frac{m_i f_{i,\ell}^2}{\sum_i m_i f_{i,\ell}^2} = \frac{m_i f_{i,\ell}^2}{\lambda_{\ell}} \quad \text{and} \quad b_{j,\ell} = \frac{c_j g_{j,\ell}^2}{\sum_j c_j g_{j,\ell}^2} = \frac{c_j g_{j,\ell}^2}{\lambda_{\ell}}. \quad (39)$$

Contributions help locate the observations important for a given factor. An often used rule of thumb is to consider that the important contributions are those larger than the average contribution, which is equal to one divided by the number of elements (i.e., $\frac{1}{I}$ for the rows and $\frac{1}{J}$ for the columns). A dimension is then interpreted by opposing the positive elements with large contributions to the negative elements with large contributions. Cosines and contributions for the punctuation example are given in Tables 3 and 4.

Inferences for Correspondence Analysis

CA was first developed as a *descriptive* multivariate method, but recently it also started to incorporate some inferential aspects. When CA analyzes a contingency table, the inertia decomposed by CA is proportional to χ^2 (see Equation 22) and, therefore an independence χ^2 statistic with $(I-1)(J-1)$ degrees of freedom implements an *omnibus* test for CA. For our example, the value of the independence χ^2 is equal to

$$\chi^2 = \mathcal{I} \times x_{+,+} = 1,424,951 \times (0.0178 + 0.0056) = 1,424,951 \times 0.0234 = 33,340.15. \quad (40)$$

When compared to a χ^2 distribution with $(6-1)(3-1) = 10$ degrees of freedom, the value of the $\chi^2 = 33,340.15$ statistic indicates that the result is highly significant and that we can confidently conclude that the authors do differ how they punctuate (even

though the differences are quite small as indicated by a value of $\varphi^2 = 0.0234$).

Malinvaud and Saporta extended this χ^2 based statistical approach to test the significance of the dimensions extracted by CA. To do so, they defined a χ^2 -like statistics denoted Q'_{ℓ} , with ℓ taking values between 0 and $L = \min(I, J) - 2$, computed as:

$$Q'_{\ell} = x_{+,+} \left(\sum_{k=\ell+1}^L \lambda_k \right). \quad (41)$$

Under the same statistical assumptions as the independence χ^2 , the statistics Q'_{ℓ} follows a χ^2 distribution with $v = (I - \ell - 1)(J - \ell - 1)$. When $\ell = 0$, $Q'_0 = \chi^2 = 33,340.15$ with a number of degrees of freedom equal to $(I-1)(J-1) = 10$ (see Equation 22) and is identical to the χ^2 statistics from Equation 40. The significance of Dimension 1 is tested by computing Q'_1 as:

$$\begin{aligned} Q'_1 &= x_{+,+} \left(\sum_{k=1+1}^2 \lambda_k \right) = x_{+,+} \left(\sum_{k=2}^2 \lambda_k \right) \\ &= x_{+,+} \times \lambda_2 = 1,424,951 \times 0.0056 = 7,949.57, \end{aligned} \quad (42)$$

a value distributed as χ^2 with $v = (I - \ell - 1)(J - \ell - 1) = 4 \times 1 = 4$ degrees of freedom. Here again, the large value of χ^2 indicates that Dimension 1 is highly significant (even though it describes a small effect as indicated by the eigenvalue of $\lambda_1 = 0.0178$). Note that Q'_{ℓ} is not defined for the last dimension of CA.

When the data matrix to be analyzed is not a true contingency table, the Q'_{ℓ} statistic is not distributed as χ^2 , and so this distribution cannot be derived analytically; So, here appropriate permutation or Monte Carlo cross-validation approaches need to be implemented to derive the sampling distribution of Q'_{ℓ} .

Multiple Correspondence Analysis

CA works with a contingency table that is equivalent to the analysis of two nominal variables (i.e., one for the rows and one for the columns). Multiple correspondence analysis (MCA) is an extension of CA, which allows the analysis of the pattern of relationship among several nominal variables. MCA is used to analyze a set of observations described by a set of nominal variables. Each nominal variable comprises several levels, and each of these levels is coded as a binary variable. For example, gender (F vs. M) is a nominal variable with two levels. The pattern for a male respondent will be coded as [01] and as [10] for a female. The complete data table is composed of binary columns with one and only one column taking the value "1" per nominal variable.

MCA can also accommodate quantitative variables by recoding them as *bins*. For example, a score with a range of -5 to $+5$ could be recoded as a nominal variable with three levels: less than 0, equal to 0, or more than 0. With this schema, a value of 3 will be expressed by the pattern [001]. The coding schema of MCA implies that each row has the same total, which for CA implies that each row has the same mass.

Essentially, MCA is computed by using a CA program on the data table. It can be shown that the binary coding scheme used in MCA creates artificial factors and therefore artificially reduces the inertia explained by the first factors of the analysis. A solution to this problem is to correct the eigenvalues obtained from the CA program; note that recent statistical packages are likely to implement this correction.

CORRESPONDENCE PRINCIPLE

The correspondence principle is generally known as the Bohr correspondence principle (CP), for Niels Bohr. It is considered one of Bohr's greatest contributions to physics, along with his derivation of the Balmer formula. Bohr's leading idea is that classical physics, though limited in scope, is indispensable for the understanding of quantum physics. The idea that old science is "indispensable" to the understanding of new science is in fact the main theme in using the concept of correspondence; therefore, the CP can be defined as the principle by which new theories of science (physics in particular) can relate to previously accepted theories in the field by means of approximation at a certain limit. Historically, Max Planck had introduced the concept in 1906. Bohr's first handling of the concept was in his first paper after World War I, in which he showed that quantum formalism would lead to classical physics when $n \rightarrow \infty$, where n is the quantum number. Although there were many previous uses of the concept, the important issue here is not to whom the concept can be attributed, but an understanding of the various ways that it can be used in scientific and philosophical research.

The principle is important for the continuity in science. There are two ways of thinking about such continuity. A theory T covers a set of observations S . A new observation s_1 is detected. T cannot explain s_1 . Scientists first try to adapt T to be able to account for s_1 . But if T is not in principle able to explain s_1 , then scientists will start to look for another theory, T^* , that can explain S and s_1 . The scientist will try to derive T^* by using CP as a determining factor. In such a case, T^* should lead to T at a certain limit.

Nonetheless, sometimes there may be a set of new observations, S_1 , for which it turns out that a direct derivation of T^* from T that might in principle account for S_1 is not possible or at least does not seem to be

possible. Then the scientist will try to suggest T^* separately from the accepted set of boundary conditions and the observed set of S and S_1 . But because T was able to explain the set of it is highly probable that T has a certain limit of correct assumptions that led to its ability to explain S . Therefore, any new theory T^* that would account for S and S_1 should resemble T at a certain limit. This can be obtained by specifying a certain correspondence limit at which the new formalism of T^* will lead to the old formalism of T .

These two ways of obtaining T^* are the general forms of applying the correspondence principle. Nevertheless, the practice of science presents us with many ways of connecting T^* to T or parts of it. Hence it is important to discuss the physicists' different treatments of the CP. Moreover, the interpretation of CP and the implications of using CP will determine our picture of science and the future development of science; hence, it is important to discuss the philosophical implications of CP and the different philosophical understandings of the concept.

Formal Correspondence

In the current state of the relation between modern physics and classical physics, there are four kinds of formal correspondence between modern and classical physics.

Old Correspondence Principle (Numerical Correspondence)

Planck stressed the relation between his "radical" assumption of discrete energy levels that are proportional to frequency, and the classical theory. He insisted that the terms in the new equation refer to the very same classical properties. He formulated the CP so that the numerical value of

$$\lim_{h \rightarrow 0} [\text{Quantum physics}] = [\text{Classical physics}]$$

He demonstrated that the radiation law for the energy density at frequency ν ,

$$u(\nu) = \frac{8\pi h \nu^3}{c^3 (e^{h\nu/kT} - 1)}, \quad (1)$$

corresponds numerically in the limit $h \rightarrow 0$ to the classical Rayleigh-Jeans law:

$$u(\nu) = \frac{8\pi k T \nu^2}{c^3}, \quad (2)$$

where k is Boltzmann's constant, T is the temperature, and c is the speed of light. This kind of correspondence entails that the new theory should resemble the old one not just at the mathematical level but also at the conceptual level.

Configuration Correspondence Principle (Law Correspondence)

The configuration correspondence principle claims that the laws of new theories should correspond to the laws of the old theory. In the case of quantum and classical physics, quantum laws correspond to the classical laws when the probability density of the quantum state coincides with the classical probability density. Take, for example, a harmonic oscillator that has a classical probability density

$$P_C(x) = 1/\left(\pi\sqrt{x_0^2 - x^2}\right), \quad (3)$$

where x is the displacement. Now if we superimpose the plot of this probability onto that of the quantum probability density $|\psi_n|^2$ of the eigenstates of the system and take (the quantum number) $n \rightarrow \infty$, we will obtain Figure 1 here. As Richard Liboff, a leading expert in the field, has noted, the classical probability density P_C does not follow the quantum probability density $|\psi_n|^2$. Instead, it follows the local average in the limit of large quantum numbers n :

$$P_C(x) = \langle P_Q(x) \rangle = \langle |\psi_n|^2 \rangle = \frac{1}{2\epsilon} \int_{x-\epsilon}^{x+\epsilon} |\psi_n(y)|^2 dy. \quad (4)$$

Frequency Correspondence Principle

The third type of correspondence is the officially accepted form of correspondence that is known in quantum mechanics books as the Bohr Correspondence Principle. This claims that the classical results should emerge as a limiting case of the quantum results in the limits $n \rightarrow \infty$ (the quantum number) and $h \rightarrow 0$ (Planck's constant). Then in the case of frequency, the quantum value should be equal to the classical value, i.e., $\nu_Q = \nu_C$. In most cases in quantum mechanics, the quantum frequency coalesces with the classical frequency in the limit $n \rightarrow \infty$ and $h \rightarrow 0$.

Nevertheless, $n \rightarrow \infty$ and $h \rightarrow 0$ are not universally equivalent, because in some cases of the quantum systems, the limit $n \rightarrow \infty$ does not yield the classical one, while the limit $h \rightarrow 0$ does; the two results are not universally equivalent. The case of a particle trapped in a cubical box would be a good example: the frequency in the high quantum number domain turns out to be displaced as

$$\nu_q^{n+1} = \nu_q^n + h/2md,$$

where m is the particle's mass and d is the length of the box. Such a spectrum does not collapse toward the classical frequency in the limit of large quantum numbers, while the spectrum of the particle does degenerate to the classical continuum in the limit $h \rightarrow 0$. It can be argued

Figure 1 Classical Versus Quantum Probability Density

that such correspondence would face another obvious problem relating to the assumption that Planck's constant goes to zero. What is the meaning of saying that "a constant goes to zero?" A constant is a number that has the same value at all times, and having it as zero is contradictory, unless it is zero. A reply to this problem might be that in correspondence, we ought to take the real limiting value and not the abstract one. In the case of relativity, the limit, "c goes to infinity" is an abstract one, and the real limit should be "v/c goes to zero." Now, when dealing with corresponding quantum mechanics to classical mechanics, one might say that we ought to take the limit $n \rightarrow \infty$ as a better one than $\hbar \rightarrow 0$. The point here is that values like c and h are constants and would not tend to go to zero or to infinity, but n and v/c are variables $-n = (0, 1, 2, 3, \dots)$ and v/c varies between 0 (when v = 0) and 1 (when v = c). (Of course, this point can also count against the old CP of Planck, the first correspondence principle in our list, because it is built on the assumption that the limit is of Planck's constant going to zero.)

Form Correspondence Principle

The last type of correspondence is form CP, which claims that we can obtain correspondence if the functional (mathematical) form of the new theory is the same as that of the old theory. This kind of correspondence is especially fruitful in particular cases in which other kinds of correspondence do not apply. Let us take the example used in frequency correspondence (quantum frequency). As seen in the case of the particle in a cubical box, the outcome of $n \rightarrow \infty$ does not coincide with the outcome of $\hbar \rightarrow 0$. Hence the two limits fail to achieve the same result. In cases such as this, form correspondence might overcome the difficulties facing frequency correspondence. The aim of form correspondence is to prove that classical frequency and quantum frequency have the same

form. So, if ν_Q denotes quantum frequency, ν_C classical frequency, and E energy, then form correspondence is satisfied if $\nu_C(E)$ has the same functional form as $\nu_Q(E)$. Then, by using a dipole approximation, Liboff showed that the quantum transition between state s+n and state s where $s \gg n$ gives the relation

$$\nu_Q^n(E) \approx n(E_s / 2ma^2)^{1/2}. \quad (5)$$

He also noticed that if we treat the same system classically (particles of energy E in a cubical box), the calculation of the radiated power in the nth vibrational mode is given by the expression

$$\nu_C^n(E) \approx n(E / 2ma^2)^{1/2}. \quad (6)$$

Both frequencies have the same form, even if one is characterizing quantum frequency and the other classical, and even if their experimental treatment differs. Hence, form CP is satisfied.

But such correspondence is not problem free; in the classical case, E denotes the average energy value of an ensemble of nth harmonic frequency, but in the quantum case, it denotes the eigenenergy of that level. Also, in the quantum case, the energy is discrete, and the only way to assert that the quantum frequency yields the classical one is by saying that when the quantum number is very big, the number of points that coincide with the classical frequency will increase, using the dipole approximation, which asserts that the distance between the points in the quantum case is assumed small. Hence the quantum case does not resemble the classical case as such, but it coincides with the average of an ensemble of classical cases.

The main thrust of form correspondence is that it can relate a branch of physics to a different branch on the basis of form resemblance, such as in the case of superconductivity. Here, a quantum formula corresponds to classical equations if we can change the quantum formula in the limit into a form where it looks similar to a classical form. The case of Josephson junctions in superconductivity, which are an important factor in building superconducting quantum interference devices, presents a perfect demonstration of such concept.

Brian David Josephson proved that the relation between the phase difference and the voltage is given by $\frac{\partial \delta}{\partial t} = \frac{2e}{\hbar} V$, that is, the voltage $V = \frac{\hbar}{2e} \frac{\partial \delta}{\partial t}$. Now, by the assertion that the Josephson junction would behave as a classical circuit, the total current would be

$$I = I_c \sin \delta + \frac{\eta}{2\text{Re}} \frac{d\delta}{dt} + \frac{\eta C}{2e} \frac{d^2 \delta}{dt^2}. \quad (7)$$

This equation relates the current with the phase difference but without any direct reference to the voltage. Furthermore, if we apply form correspondence, Equation 7 is analogous to the equation of a pendulum in classical mechanics. The total torque τ on the pendulum would be

$$\tau = M \frac{d^2\theta}{dt^2} + D \frac{d\theta}{dt} + \tau_0 \sin \theta, \quad (8)$$

where M is the moment of inertia, D is the viscous damping, and τ is the applied torque.

Both these equations have the general mathematical form

$$Y = Y_0 \sin x + B \frac{dx}{dt} + A \frac{d^2x}{dt^2}. \quad (9)$$

This kind of correspondence can be widely used to help in the solution of many problems in physics. Therefore, to find new horizons in physics, some might even think of relating some of the new theories that have not yet applied CP. Such is the case with form corresponding quantum chaos to classical chaos. The argument runs as follows: Classical chaos exists. If quantum mechanics is to be counted as a complete theory in describing nature, then it ought to have a notion that corresponds to classical chaos. That notion can be called quantum chaos. But what are the possible things that resemble chaotic behavior in quantum systems? The reply gave rise to quantum chaos. However, it turns out that a direct correspondence between the notion of chaos in quantum mechanics and that in classical mechanics does not exist.

Therefore, form correspondence would be fruitful here. Instead of corresponding quantum chaos to classical chaos, we can correspond both of them to a third entity. Classical chaos goes in a certain limit to the form ϕ , and quantum chaos goes to the same form at the same limit:

$$\lim_{n \rightarrow \infty} \text{classical chaos} = \phi$$

$$\lim_{n \rightarrow \infty} \text{quantum chaos} = \phi,$$

but because we have only classical and quantum theories, then the correspondence is from one to the other, as suggested by Gordon Belot and John Earman.

In addition to these four formal forms of correspondence, many other notions of correspondence might apply, such as *conceptual correspondence*, whereby new concepts ought to resemble old concepts at the limited range of applicability of such concepts. In addition, there is *observational correspondence*, which is a

weak case of correspondence whereby the quantum will correspond to what is expected to be observed classically at a certain limit. *Structural correspondence* combines elements from both form correspondence and law correspondence. Hence, scientific practice might need different kinds of correspondence to achieve new relations and to relate certain domains of applicability to other domains.

Philosophical Implications

Usually, principles in science, such as the Archimedes principle, are universally accepted. This is not the case with CP. Although CP is considered by most physicists to be a good heuristic device, it is not accepted across the board. There are two positions: The first thinks of development in science as a mere trial-and-error process; the second thinks that science is progressive and mirrors reality, and therefore new theories cannot cast away old, successful theories but merely limit the old ones to certain boundaries.

Max Born, for example, believed that scientists depend mainly on trial and error in a shattered jungle, where they do not have any signposts in science, and it is all up to them to discover new roads in science. He advised scientists to rely not on “abstract reason” but on experience. However, to accept CP means that we accept abstract reason; it also means that we do not depend on trial and error but reason from whatever accepted knowledge we have to arrive at new knowledge.

The philosophical front is much more complex. There are as many positions regarding correspondence as there are philosophers writing on the subject. But in general, realists are the defenders of the concept, whereas positivists, instrumentalists, empiricists, and antirealists are, if not opposed to the principle, then indifferent about it. Some might accept it as a useful heuristic device, but that does not give it any authoritarian power in science.

Even among realists there is more than one position. Some such as Elie Zahar claim that the CP influence ought to stem from old theory and arrive at the new through derivative power. Heinz Post is more flexible; he accepts both ways as legitimate and suggests a *generalized correspondence principle* that ought to be applied to all the developments in science. In doing so, he is replying to Thomas Kuhn’s *Structure of Scientific Revolutions*, rejecting Kuhn’s claim of paradigm shift and insisting on scientific continuity. In doing so, Post is also rejecting Paul Feyerabend’s concept of incommensurability.

So is CP really needed? Does correspondence relate new theories to old ones, or are the new theories deduced

from old theories using CP? Can old theories really be preserved? Or what, if anything, can be preserved from the old theories? What about incommensurability between the new and the old? How can we look at correspondence in light of Kuhn's concept of scientific revolution? What happens when there is a paradigm shift? All these questions are in fact related to our interpretation of CP.

CP, realists say, would help us in understanding developments in science as miracle free (the no-miracle argument). Nevertheless, by accepting CP as a principle that new theories should uphold, we in effect are trapped within the scope of old theories. This means that if our original line of reasoning was wrong and still explains the set of observations that we obtained, then the latter theory that obeys CP will resolve the problems of the old theory within a certain limit, will no doubt continue to hold the posits of the wrong theory, and will continue to abide by its accepted boundary conditions. This means that we will not be able to see where old science went wrong. In reply, conventional realists and structural realists would argue that the well-confirmed old theories are good representations of nature, and hence any new theories should resemble them at certain limits. Well, this is the heart of the matter. Even if old theories are confirmed by experimental evidence, this is not enough to claim that the abstract theory is correct. Why? Mathematically speaking, if we have any finite set of observations, then there are many possible mathematical models that can describe this set. Hence, how can we determine that the model that was picked by the old science was the right one?

But even if we accept CP as a heuristic device, there are many ways that the concept can be applied. Each of these ways has a different set of problems for realists, and it is not possible to accept any generalized form of correspondence.

The realist position was challenged by many philosophers. Kuhn proved that during scientific revolutions the new science adopts a new paradigm in which the workings of the old science might continue, but with different meanings. He demonstrated such a change with mass: The concept of mass in relativity is not the same as Newtonian mass. Feyerabend asserted that the changes between new science and old science make them incommensurable with each other. Hence, the realist notion of approximating new theories to old ones is going beyond the accepted limits of approximation.

The other major recent attacks on realism come from pessimistic metainduction (Larry Laudan) on one hand and new versions of empiricist arguments (Bas van Fraassen) on the other. Van Fraassen defines his position as *constructive empiricism*. Laudan relies on the history of science to claim that the realists' explanation of the successes of science does not hold. He argues that the success of theories cannot offer grounds for accepting that these

theories are true (or even approximately true). He presents a list of theories that have been successful and yet are now acknowledged to be false. Hence, he concludes, depending on our previous experience with scientific revolutions, the only reasonable induction would be that it is highly probable that our current successful theories will turn out to be false. Van Fraassen claims that despite the success of theories in accounting for phenomena (their empirical adequacy), there can never be any grounds for believing any claims beyond those about what is observable. That is, we cannot say that such theories are real or that they represent nature; we can only claim that they can account for the observed phenomena.

Recent trends in realism tried to salvage realism from these attacks, but most of these trends depend on claiming that we do not need to save the old theory as a whole; we can save only the representative part. Structural realists, such as John Worrell and Elie Zahar, claim that only the mathematical structure need be saved and that CP is capable of assisting us in saving it. Philip Kitcher asserts that only presupposition posits can survive. Towfic Shomar claims that the dichotomy should be horizontal rather than vertical and that the only parts that would survive are the phenomenological models (phenomenological realism). Stathis Psillos claims that scientific theories can be divided into two parts, one consisting of the claims that contributed to successes in science (working postulates) and the other consisting of idle components.

Hans Radder, following Roy Bhaskar, thinks that progress in science is like a production line: There are inputs and outputs; hence our old knowledge of theories and observations is the input that dictates the output (our new theories). CP is important in the process; it is a good heuristic device, but it is not essential, and in many cases it does not work.

But is CP a necessary claim for all kinds of realism to account for developments in science? Some, including Shomar, do not think so. Nancy Cartwright accepts that theories are mere tools; she thinks that scientific theories are patchwork that helps in constructing models that represent different parts of nature. Some of these models depend on tools borrowed from quantum mechanics and account for phenomena related to the microscopic world; others use tools from classical mechanics and account for phenomena in the macroscopic world. There is no need to account for any connection between these models. Phenomenological realism, too, takes theories as merely tools to construct phenomenological models that are capable of representing nature. In that case, whether the fundamental theories correspond to each other to some extent or not is irrelevant. The correspondence of theories concerns realists who think that fundamental theories represent nature and approximate its blueprint.

Currently, theoretical physics is facing a deadlock; as Lee Smolin and Peter Woit have argued, the majority of theoretical physicists are running after the unification of all forces and laws of physics. They are after the theory of everything. They are convinced that science is converging toward a final theory that represents the truth about nature. They are in a way in agreement with the realists, who hold that successive theories of “mature science” approximate the truth more and more, so science should be in quest of the final theory of the final truth.

Theoretical representation might represent the truth about nature, but we can easily imagine that we have more than one theory to depend on. Nature is complex, and in light of the richness of nature, which is reflected in scientific practice, one may be unable to accept that Albert Einstein’s request for simplicity and beauty can give the correct picture of current science when complexity and diversity appear to overshadow it. The complexity of physics forces some toward a total disagreement with Einstein’s dream of finding a unified theory for everything. To some, such a dream directly contradicts the accepted theoretical representations of physics. Diversity and complexity are the main characteristics of such representations.

Nonetheless, CP is an important heuristic device that can help scientists arrive at new knowledge, but scientists and philosophers should be careful as to how much of CP they want to accept. As long as they understand and accept that there is more than one version of CP and as long as they accept that not all new theories can, even in principle, revert to old theories at a certain point, then they might benefit from applying CP. One other remark of caution: Scientists and philosophers also need to accept that old theories might be wrong; the wrong mathematical form may have been picked, and if they continue to accept such a form, they will continue to uphold a false science.

COVARIATE

Similar to an independent variable, a covariate is complementary to the dependent, or response, variable. A variable is a covariate if it is related to the dependent variable. According to this definition, any variable that is measurable and considered to have a statistical relationship with the dependent variable would qualify as a potential covariate. A covariate is thus a possible predictive or explanatory variable of the dependent variable. This may be the reason that in regression analyses, independent variables (i.e., the *regressors*) are sometimes called covariates. Used in this context, covariates are of primary interest. In most other circumstances, however, covariates are of no primary interest compared with the independent variables. They arise because the experimental or observational units are heterogeneous. When this occurs, their existence is mostly a nuisance because they may interact with the independent variables to obscure the true relationship between the dependent and the independent variables. It is in this circumstance that one needs to be aware of and make efforts to control the effect of covariates. Viewed in this context, covariates may be called by other names, such as concomitant variables, auxiliary variables, or secondary variables. This entry discusses methods for controlling the effects of covariates and provides examples.

Controlling Effects of Covariates

Research Design

Although covariates are neither the design variable (i.e., the independent variable) nor the primary outcome (e.g., the dependent variable) in research, they are still

explanatory variables that may be manipulated through experiment design so that their effect can be eliminated or minimized. Manipulation of covariates is particularly popular in controlled experiments. Many techniques can be used for this purpose. An example is to fix the covariates as constants across all experimental treatments so that their effects are exerted uniformly and can be canceled out. Another technique is through *randomization* of experimental units when assigning them to the different experimental treatments. Key advantages of randomization are (a) to control for important known and unknown factors (the control for unknown factors is especially significant) so that all covariate effects are minimized and all experimental units are statistically comparable on the mean across treatments, (b) to reduce or eliminate both intentional and unintentional human biases during the experiment, and (c) to properly evaluate error effects on the experiment because of the sound probabilistic theory that underlies the randomization. Randomization can be done to all experimental units at once or done to experimental units within a block. Blocking is a technique used in experimental design to further reduce the variability in experimental conditions or experimental units. Experimental units are divided into groups called blocks, and within a group, experimental units (or conditions) are assumed to be homogeneous, although they differ between groups.

However ideal, there is no guarantee that randomization eliminates all covariate effects. Even if it could remove all covariate effects, randomization may not always be feasible due to various constraints in an experiment. In most circumstances, covariates, by their nature, are not controllable through experiment designs. They are therefore not manipulated and allowed to vary naturally among experimental units across treatments. Under such circumstances, their value is often observed, together with the value of the dependent variables. The observation can be made either before, after, or during the experiment, depending on the nature of the covariates and their influence on the dependent variables. The value of a covariate may be measured prior to the administration of experimental treatments if the status of the covariate before entering into the experiment is important or if its value changes during the experiment. If the covariate is not affected by the experimental treatments, it may be measured after the experiment. The researcher, however, should be mindful that measuring a covariate after an experiment is done carries substantial risks unless there is strong evidence to support such an assumption. In the hypothetical nutrition study example given below, the initial height and weight of pupils are not covariates that can be measured after the experiment is carried out. The reason is that both height and weight are the response variables of the experiment, and they

are influenced by the experimental treatments. In other circumstances, the value of the covariate is continuously monitored, along with the dependent variable, during an experiment. An example may be the yearly mean of ocean temperatures in a long-term study by R. J. Beamish and D. R. Bouillon of the relationship between the quotas of salmon fish harvested in the prior year and the number of salmon fish returned to the spawning ground of the rivers the following year, as prior research has shown that ocean temperature changes bear considerable influence on the life of salmon fish.

Statistical Analysis

After the covariates are measured, a popular statistical procedure, the analysis of covariance (ANCOVA), is then used to analyze the effect of the design variables on the dependent variable by explicitly incorporating covariates into the analytical model. Assume that an experiment has n design variables and m covariates; a proper statistical model for the experiment would be

$$y_{ij} = \mu + t_i + \sum_{k=1}^m \beta_k (x_{kij} - \bar{x}_{k..}) + \varepsilon_{ij}$$

where y_{ij} is the j th measurement on the dependent variable (i.e., the primary outcome) in the i th treatment; μ is the overall mean; t_i is the i th design variable (often called treatment in experiment design); x_{kij} is the measurement on the k th covariate corresponding to y_{ij} ; $\bar{x}_{k..}$ is the mean of the x_{kij} values; β_k is a linear (partial) regression coefficient for the k th covariate, which emphasizes the relationship between x_{kij} and y_{ij} ; and ε_{ij} is a random variable that follows a specific probability distribution with zero mean. An inspection of this ANCOVA model reveals that it is in fact an integration of an analysis of variance (ANOVA) model with an ANOVA of regression model. The regression part is on the covariates (recall that regressors are sometimes called covariates). A test on the hypothesis $H_0: \beta_k = 0$ confirms or rejects the null hypothesis of no effect of covariates on the response variable. If no covariate effects exist, Equation 1 is then reduced to an ordinary ANOVA model.

Before Equation 1 can be used, though, one needs to ensure that the assumption of homogeneity of regression slopes is met. Tests must be carried out on the hypothesis that $\beta_1 = \beta_2 = \dots = \beta_k = 0$. In practice, this is equivalent to finding no interaction between the covariates and the independent variables on the dependent variable. Without meeting this condition, tests on the adjusted means of the treatments are invalid. The reason is that when the slopes are different, the response of the treatments varies at the different levels of the covariates. Consequently, the adjusted means do not adequately describe the treatment effects, potentially resulting in misleading conclusions. If

tests indeed confirm heterogeneity of slopes, alternative methods can be sought in lieu of ANCOVA, as described by Bradley Eugene Huitema. Research has repeatedly demonstrated that even randomized controlled trials can benefit from ANCOVA in uncovering the true relationship between the independent and the dependent variables.

It must be pointed out that regardless of how the covariates are handled in a study, their value, like that of the independent variables, is seldom analyzed separately because the covariate effect is of no primary interest. Instead, a detailed description of the covariates is often given to assist the reader in evaluating the results of a study. According to Fred Ramsey and Daniel Schafer, the incorporation of covariates in an ANCOVA statistical model is (a) to control for potential confounding, (b) to improve comparison across treatments, (c) to assess model adequacy, and (d) to expand the scope of inference. The last point is supported by the fact that the experiment is conducted in a more realistic environment that allows a covariate to change naturally, instead of being fixed at a few artificial levels, which may or may not be representative of the true effect of the covariate on the dependent variable.

From what has been discussed so far, it is clear that there is no fixed rule on how covariates should be dealt with in a study. Experiment control can eliminate some obvious covariates, such as ethnicity, gender, and age in a research on human subjects, but may not be feasible in all circumstances. Statistical control is convenient, but covariates need to be measured and built into a model. Some covariates may not be observable, and only so many covariates can be accommodated in a model. Omission of a key covariate could lead to severely biased results. Circumstances, therefore, dictate whether to control the effect of covariates through experiment design measures or to account for their effect in the data analysis step. A combination of experimental and statistical control is often required in certain circumstances. Regardless of what approach is taken, the ultimate goal of controlling the covariate effect is to reduce the experimental error so that the treatment effect of primary interest can be elucidated without the interference of covariates.

Examples

To illustrate the difference between covariate and independent variables, consider an agricultural experiment on the productivity of two wheat varieties under two fertilization regimes in field conditions, where productivity is measured by tons of wheat grains produced per season per hectare (1 hectare = 2.47 acres). Although researchers can precisely control both the wheat varieties and the fertilization regimes as the primary independent variables

of interest in this specific study, they are left to contend with the heterogeneity of soil fertility, that is, the natural micro variation in soil texture, soil structure, soil nutrition, soil water supply, soil aeration, and so on. These variables are natural phenomena that are beyond the control of the researchers. They are the covariates. By themselves alone, these covariates can influence the productivity of the wheat varieties. Left unaccounted for, these factors will severely distort the experimental results in terms of wheat produced. The good news is that all these factors can be measured accurately with modern scientific instruments or methodologies. With their values known, these variables can be incorporated into an ANCOVA model to account for their effects on the experimental results.

In health research, suppose that investigators are interested in the effect of nutrition on the physical development of elementary school children between 6 and 12 years of age. More specifically, the researchers are interested in the effect of a particular commercial dietary regime that is highly promoted in television commercials. Here, physical development is measured by both height and weight increments without the implication of being obese. In pursuing their interest, the researchers choose a local boarding school with a reputation for excellent healthy nutritional programs. In this study, they want to compare this commercial dietary regime with the more traditional diets that have been offered by the school system for many years. They have done all they can to control all foreseeable potential confounding variables that might interfere with the results on the two dietary regimes. However, they are incapable of controlling the initial height and weight of the children in the study population. Randomized assignments of participating pupils to the treatment groups may help minimize the potential damage that the natural variation in initial height and weight may cause to the validity of the study, but they are not entirely sure that randomization is the right answer to the problem. These initial heights and weights are the covariates, which must be measured before (but not after) the study and accounted for in an ANCOVA model in order for the results on dietary effects to be properly interpreted.

Final Thoughts

Covariates are explanatory variables that exist naturally within research units. What differentiates them from independent variables is that they are of no primary interest in an investigation but are nuisances that must be dealt with. Various control measures are placed on them at either the experiment design or the data analysis step to minimize the experimental error so that the treatment effects on the major outcome can be better understood. Without these

measures, misleading conclusions may result, particularly when major covariates are not properly dealt with.

Regardless of how one decides to deal with the covariate effects, either by experimental control or by data analysis techniques, one must be careful not to allow the covariate to be affected by the treatments in a study. Otherwise, the covariate may interact with the treatments, making a full accounting of the covariate effect difficult or impossible.

CRITERION PROBLEM

The term *criterion problem* refers to a general problem in regression analysis, especially when used for selection, when the criterion measure that is easily obtainable is not a good approximation of the actual criterion of interest. In other words, the criterion problem refers to the problem that measures of the criterion performance behaviors in which the researcher or practitioner is interested in predicting are not readily available. For example, although specific sets of performance behaviors are desirable in academic and employment settings, often the easily obtainable measures are 1st-year grade point averages (GPAs) and supervisory ratings of job performance. The criterion problem is that those easily obtainable measures (GPA and supervisory performance ratings) are not good measures of important performance behaviors. The criterion is said to be deficient if

important performance behaviors are not captured in a particular criterion measure. It can also be considered contaminated if the criterion measure also assesses things that are unrelated to the performance behaviors of interest. This entry explores the criterion problem in both academic and employment settings, describes how the criterion problem can be addressed, and examines the implications for selection research.

Criterion Problem in Academic Settings

In academic settings, there are two typical and readily available criterion variables: GPA and student retention (whether a student has remained with the university). Although each of these criteria is certainly important, most researchers agree that there is more to being a good student than simply having good grades and graduating from the university. This is the essence of the criterion problem in academic settings: The specific behaviors that persons on the admissions staff would like to predict are not captured well in the measurement of the readily available GPA and retention variables. The first step in solving the criterion problem, then, is identifying which types of behaviors are important.

Thomas Taber and Judith Hackman provided one of the earliest attempts to model the performance behaviors relating to effective performance in undergraduate college students. After surveying many university students, staff, and faculty members, they identified 17 areas of student performance and two broad categories: academic performance and nonacademic performance. The academic performance factors, such as cognitive proficiency, academic effort, and intellectual growth, are reasonably measured in the easily obtained overall GPA; these factors are also predicted fairly well by the traditional variables that predict GPA (e.g., standardized tests, prior GPA). The nonacademic performance factors, on the other hand, are not captured well in the measurement of GPA. These factors include ethical behavior, discrimination issues, and personal growth, and none of these are well predicted by traditional predictor variables.

In more recent research, Frederick Oswald and colleagues modeled undergraduate student performance for the purposes of scale construction. By examining university mission statements across a range of colleges to determine the student behaviors in which stakeholders are ultimately interested, they identified 12 performance factors that can be grouped into three broad categories: intellectual, interpersonal, and intrapersonal. Intellectual behaviors are best captured with GPA and include knowledge, interest in learning, and artistic appreciation. Interpersonal behaviors include leadership, interpersonal skills, social responsibility, and multicultural tolerance.

Intrapersonal behaviors include health, ethics, perseverance, adaptability, and career orientation. However, GPA does not measure the interpersonal or intrapersonal behaviors particularly well. It is interesting to note that this research also showed that while traditional predictors (e.g., standardized tests, prior GPA) predict college GPA well, they do not predict the nonintellectual factors; non-cognitive variables, such as personality and scales developed to assess these performance dimensions, are much better predictors of the nonintellectual factors.

Criterion Problem in Employment Settings

In employment settings, the criterion problem takes a different form. One readily available criterion for many jobs is the so-called objective performance indicator. In manufacturing positions, for example, the objective performance indicator could be number of widgets produced; in sales, it could be the dollar amount of goods sold. With these measures of performance, the criterion problem is one of contamination; external factors not under the control of the employee also heavily influence the scores on these metrics. In manufacturing positions, the availability or maintenance of the equipment can have a substantial influence on the number of widgets produced; these outside influences are entirely independent of the behavior of the employee. In sales positions, season or differences in sales territory can lead to vast differences in the dollar amount of goods sold; again, these outside influences are outside the behavioral control of the employee. Such outside influences are considered criterion contamination because although they are measured with the criterion, they have nothing to do with the behaviors of interest to the organization. Unfortunately, most of these objective criterion measures suffer from contamination without possibility of better measurement for objective metrics.

Another form of the criterion problem in employment settings concerns supervisory ratings of job performance. These supervisory ratings are by far the most common form of performance evaluation in organizations. In these situations, the criterion problem concerns what, exactly, is being measured when a supervisor is asked to evaluate the performance of an employee. Although this problem has been the subject of much debate and research for the better part of a century, some recent research has shed substantial light on the issue.

John Campbell and colleagues, after doing extensive theoretical, exploratory, statistical, and empirical work in the military and the civilian workforce, developed an eight-factor taxonomy of job performance behaviors. These eight factors included job-specific task proficiency, non-job-specific task proficiency, written and oral communication, demonstration of

effort, maintenance of personal discipline, facilitation of peer and team performance, supervision or leadership, and management or administrative duties. Two key elements here are of particular importance to the criterion problem. First, these are eight factors of performance *behaviors*, specifically limiting the criterion to aspects that are under the direct control of the employee and eliminating any contaminating factors. Second, these eight factors are meant to be exhaustive of all types of job performance behaviors; in other words, any type of behavior relating to an employee's performance can be grouped under one of these eight factors. Later models of performance group these eight factors under three broad factors of task performance (the core tasks relating to the job), contextual performance (interpersonal aspects of the job), and counter-productive behaviors (behaviors going against organizational policies).

Measurement of Performance

Solutions to the criterion problem are difficult to come by. The data collection efforts that are required to overcome the criterion problem are typically time, effort, and cost intensive. It is for those reasons that the criterion problem still exists, despite the fact that theoretical models of performance are available to provide a way to assess the actual criterion behaviors of interest. For those interested in addressing the criterion problem, several broad steps must be taken. First, there must be some identification of the performance behaviors that are of interest in the particular situation. These can be identified from prior research on performance modeling in the area of interest, or they can be developed uniquely in a particular research context (e.g., through the use of job analysis). Second, a way to measure the identified performance behaviors must be developed. This can take the form of a standardized questionnaire, a set of interview questions, and so forth. Also, if performance ratings are used as a way to measure the performance behaviors, identification of the appropriate set of raters (e.g., self, peer, supervisor, faculty) for the research context would fall under this step. The third and final broad step is the actual data collection on the criterion. Often, this is the most costly step (in terms of necessary resources) because prior theoretical and empirical work can be relied on for the first two steps. To complete the collection of criterion data, the researcher must then gather the appropriate performance data from the most appropriate source (e.g., archival data, observation, interviews, survey or questionnaire responses). Following these broad steps enables the researcher to address the criterion problem and develop a criterion variable much more closely related to the actual behaviors of interest.

Implications for Selection Research

The criterion problem has serious implications for research into the selection of students or employees. If predictor variables are chosen on the basis of their relations with the easily obtainable criterion measure, then relying solely on that easily available criterion variable means that the selection system will select students or employees on the basis of how well they will perform on the behaviors captured in the easily measured criterion variable, but not on the other important behaviors. In other words, if the criterion is deficient, then there is a very good chance that the set of predictors in the selection system will also be deficient. Leaetta Hough and Frederick Oswald have outlined this problem in the employment domain with respect to personality variables. They showed that if careful consideration is not paid to assessing the performance domains of interest (i.e., the criterion ends up being deficient), then important predictors can be omitted from the selection system.

The criterion problem has even more severe implications for selection research in academic settings. The vast majority of the validation work has been done using GPA as the ultimate criterion of interest. Because GPA does not capture many of the inter- and intrapersonal nonintellectual performance factors that are considered important for college students, the selection systems for college admissions are also likely deficient. Although it is certainly true that admissions committees use the available information (e.g., letters of recommendation, personal statements) to try to predict these other performance factors that GPA does not assess, the extent to which the predictors relate to these other performance factors is relatively unknown.

What is clear is that unless attention is paid to the criterion problem, the resulting selection system will likely be problematic as well. When the measured criterion is deficient, the selection system will miss important predictors unless the unmeasured performance factors have the exact same determinants as the performance factors captured in the measured criterion variable. When the measured criterion is contaminated, relationships between the predictors and the criterion variable will be attenuated, as the predictors are unrelated to the contaminating factor; when a researcher must choose a small number of predictors to be included in the selection system, criterion contamination can lead to useful predictors erroneously being discarded from the final set of predictors. Finally, when a criterion variable is simply available without a clear understanding of what was measured, it is extremely difficult to choose a set of predictors.

CRITERION VALIDITY

Also known as *criterion-related validity*, or sometimes *predictive* or *concurrent validity*, *criterion validity* is the general term to describe how well scores on one measure (i.e., a *predictor*) predict scores on another measure of interest (i.e., the *criterion*). In other words, a particular criterion or outcome measure is of interest to the researcher; examples could include (but are not limited to) ratings of job performance, grade point average (GPA) in school, a voting outcome, or a medical diagnosis. Criterion validity, then, refers to the strength of the relationship between measures intended to predict the ultimate criterion of interest and the criterion measure itself. In academic settings, for example, the criterion of interest may be GPA, and the predictor being studied is the score on a standardized math test. Criterion validity, in this context, would be the strength of the relationship (e.g., the correlation coefficient) between the scores on the standardized math test and GPA.

Some care regarding the use of the term *criterion validity* needs to be employed. Typically, the term is applied to predictors, rather than criteria; researchers often refer to the “criterion validity” of a specific predictor. However, this is not meant to imply that there is only one “criterion validity” estimate for each predictor. Rather, each predictor can have different “criterion validity” estimates for many different criteria. Extending the above example, the standardized math test may have one criterion validity estimate for overall GPA, a higher criterion validity estimate for science ability, and a lower criterion validity estimate for artistic appreciation; all three are valid criteria of interest. Additionally, each of these estimates may be moderated by (i.e., have different criterion validity estimates for) situational, sample, or research design characteristics. In this entry, the nature of a criterion variable, the research designs that assess criterion validity, effect sizes, and concerns, which may arise in applied selection are discussed. Another concern about using the term *criterion validity* is that modern researchers treat validity as a unitary concept that subsumes a variety of aspects or types of evidence or arguments, and criterion-based validity is one of those, so referring to it as a type of validity is problematic.

Nature of the Criterion

Again, the term *criterion validity* typically refers to a *specific* predictor measure, often with the criterion measure assumed. Unfortunately, this introduces substantial confusion into the procedure of criterion validation. Certainly, a single predictor measure can predict an extremely wide range of criteria, as Christopher Brand has shown with general intelligence, for example. Using the same example, the criterion validity estimates for general intelligence vary quite a bit; general intelligence predicts some criteria better than others. This fact further illustrates that there is no single criterion validity estimate for a single predictor. Additionally, the relationship between one predictor measure and one criterion variable can vary depending on other variables (i.e., moderator variables), such as situational characteristics, attributes of the sample, and particularities of the research design. Issues here are highly related to the criterion problem in predictive validation studies.

Research Design

There are four broad research designs to assess the criterion validity for a specific predictor: predictive validation, quasi-predictive validation, concurrent validation, and postdictive validation. Each of these is discussed in turn.

Predictive Validation

When examining the criterion validity of a specific predictor, the researcher is often interested in selecting persons based on their scores on a predictor (or set of predictor measures) that will predict how well the people will perform on the criterion measure. In a true predictive validation design, predictor measure or measures are administered to a set of applicants, and the researchers select applicants completely randomly (i.e., without regard to their scores on the predictor measure or measures). The correlation between the predictor measure(s) and the criterion of interest is the *index of criterion validity*. This design has the advantage of being free from the effects of range restriction; however, it is an expensive design and unfeasible in many situations, as stakeholders are often unwilling to forgo selecting on potentially useful predictor variables.

Quasi-Predictive Validation

Like a true predictive validation design, in a quasi-predictive design, the researcher is interested in administering a predictor (or set of predictors) to the applicants in order to predict their scores on a criterion variable of interest. Unlike a true predictive design, in a quasi-predictive validation design, the researcher will select applicants based on their scores on the predictor(s). As before, the correlation between the predictor(s) and the criterion of interest is the index of criterion validity. However, in a quasi-predictive design, the correlation between the predictor and criterion will likely be smaller because of range restriction due to selection on the predictor variables. Certainly, if the researcher has a choice between a predictive and quasi-predictive design, the predictive design would be preferred because it provides a more accurate estimate of the criterion validity of the predictor(s); however, quasi-predictive designs are far more common. Although quasi-predictive designs typically suffer from range restriction problems, they have the advantage of allowing the predictors to be used for selection purposes, while researchers obtain criterion validity estimates.

Concurrent Validation

In a concurrent validation design, the predictor(s) of interest to the researcher are not administered to a set of applicants; rather, they are administered only to the incumbents or people who have already been selected. The correlation between the scores on the predictors and the criterion measures for the incumbents serves as the

criterion validity estimate for that predictor or set of predictors. This design has several advantages, including cost savings due to administering the predictors to fewer people and reduced time to collection of the criterion data. However, there are also some disadvantages, including the fact that criterion validity estimates are likely to be smaller as a result of range restriction (except in the rare situation when the manner in which the incumbents were selected is completely unrelated to scores on the predictor or predictors).

Another potential concern regarding concurrent validation designs is the motivation of test takers. This is a major concern for noncognitive assessments, such as personality tests, survey data, and background information. Collecting data on these types of assessments in a concurrent validation design provides an estimate of the maximum criterion validity for a given assessment. This is because incumbents, who are not motivated to alter their scores in order to be selected, are assumed to be answering honestly. However, there is some concern for intentional distortion in motivated testing sessions (i.e., when applying for a job or admittance to school), which can affect criterion validity estimates. As such, one must take care when interpreting criterion validity estimates in this type of design. If estimates under operational selection settings are of interest (i.e., when there is some motivation for distortion), then criterion validity estimates from a predictive or quasi-predictive design are of interest; however, if estimates of maximal criterion validity for the predictor(s) are of interest, then a concurrent design is appropriate.

Postdictive Validation

Postdictive validation is an infrequently used design to assess criterion validity. At its basics, postdictive validation assesses the criterion variable first and then subsequently assesses the predictor variable(s). Typically, this validation design is not employed because the predictor variable(s), by definition, come(s) temporally before the criterion variable is assessed. However, a postdictive validation design can be especially useful, if not the only alternative, when the criterion variable is rare or unethical to obtain. Such examples might include criminal activity, abuse, or medical outcomes. In rare criterion instances, it is nearly impossible to know when the outcome will occur; as such, the predictors are collected after the fact to help predict who is at risk of the particular criterion variable. In other instances when it is extremely unethical to collect data on the criterion of interest (e.g., abuse), predictor variables are collected after the fact in order to determine who might be at risk of those criterion variables. Regardless of the reason for

the postdictive design, people who met or were assessed on the criterion variable are matched with other people who were not, typically on demographic and/or other variables. The relationship between the predictor measures and the criterion variable assessed for the two groups serves as the estimate of criterion validity.

Effect Sizes

Any discussion of criterion validity necessarily involves a discussion of effect sizes; the results of a statistical significance test are inappropriate to establish criterion validity. The question of interest in criterion validity is, To what degree are the predictor and criterion related? or How well does the measure predict scores on the criterion variable? Instead of, Are the predictor and criterion related? Effect sizes address the former questions, while significance testing addresses the latter. As such, effect sizes are necessary to quantify how well the predictor and criterion are related and to provide a way to compare the criterion validity of several different predictors.

The specific effect size to be used is dependent on the research context and types of data being collected. These can include (but are not limited to) odds ratios, correlations, and standardized mean differences. For the purposes of explanation, it is assumed that there is a continuous predictor and a continuous criterion variable, making the correlation coefficient the appropriate measure of effect size. In this case, the correlation between a given predictor and a specific criterion serves as the estimate of criterion validity. Working in the effect size metric has the added benefit of permitting comparisons of criterion validity estimates for several predictors. Assuming that two predictors were collected under similar research designs and conditions and are correlated with the same criterion variable, then the predictor with the higher correlation with the criterion can be said to have greater criterion validity than the other predictor (for that particular criterion and research context). If a criterion variable measures different behaviors or was collected under different research contexts (e.g., a testing situation prone to motivated distortion *vs.* one without such motivation), then criterion validity estimates are not directly comparable.

Statistical Artifacts

Unfortunately, several statistical artifacts can have dramatic effects on criterion validity estimates, with two of the most common being measurement error and range restriction. Both of these (in most applications) serve to lower the observed relationships from their true values.

These effects are increasingly important when one is comparing the criterion validity of multiple predictors.

Range Restriction

Range restriction occurs when there is some mechanism that makes it more likely for people with higher scores on a variable to be selected than people with lower scores. This is common in academic or employee selection as the scores on the administered predictors (or variables related to those predictors) form the basis of who is admitted or hired. Range restriction is common in quasi-predictive designs (because predictor scores are used to select or admit people) and concurrent designs (because people are selected in a way that is related to the predictor variables of interest in the study). For example, suppose people are hired into an organization on the basis of their interview scores. The researcher administers another potential predictor of the focal criterion in a concurrent validation design. If the scores on this new predictor are correlated with scores on the interview, then range restriction will occur. True predictive validation designs are free from range restriction because either no selection occurs or selection occurs in a way uncorrelated with the predictors. In postdictive validation designs, any potential range restriction is typically controlled for in the matching scenario.

Range restriction becomes particularly problematic when the researcher is interested in comparing criterion validity estimates. This is because observed criterion validity estimates for different predictors can be differentially decreased because of range restriction. Suppose that two predictors that truly have equal criterion validity were administered to a set of applicants for a position. Because of the nature of the way they were selected, suppose that for Predictor A, 90% of the variability in predictor scores remained after people were selected, but only 50% of the variability remained for Predictor B after selection. Because of the effects of range restriction, Predictor A would have a higher criterion validity estimate than Predictor B would, even though each had the same true criterion validity. In these cases, one should apply range restriction corrections before comparing validity coefficients. Fortunately, there are multiple formulas available to correct criterion validity estimates for range restriction, depending on the precise mechanism of range restriction.

Measurement Error

Unlike range restriction, the attenuation of criterion validity estimates due to unreliability occurs in all settings. Because no measure is perfectly reliable,

random measurement error will serve to attenuate statistical relationships among variables. The well-known correction for attenuation serves as a way to correct observed criterion validity estimates for attenuation due to unreliability. However, some care must be taken in applications of the correction for attenuation.

In most applications, researchers are not interested in predicting scores on the criterion *measure*; rather, they are interested in predicting standing on the criterion *construct*. For example, the researcher would not be interested in predicting the supervisory ratings of a particular employee's teamwork skills, but the researcher would be interested in predicting the true nature of the teamwork skills. As such, correcting for attenuation due to measurement error in the criterion provides a way to estimate the relationship between predictor scores and the true criterion construct of interest. These corrections are extremely important when criterion reliability estimates are different in the validation for multiple predictors. If multiple predictors are correlated with the same criterion variable in the same sample, then each of these criterion validity estimates is attenuated to the same degree. However, if different samples are used, and the criterion reliability estimates are unequal in the samples, then the correction for attenuation in the criterion should be employed before making comparisons among predictors.

Corrections for attenuation in the predictor variable are appropriate only under some conditions. If the researcher is interested in a theoretical relationship between a predictor *construct* and a criterion construct, then correcting for attenuation in the predictor is warranted. However, if there is an applied interest in estimating the relationship between a particular predictor *measure* and a criterion of interest, then correcting for attenuation in the predictor is inappropriate. Although it is true that differences in predictor reliabilities can produce artifactual differences in criterion validity estimates, these differences have substantive implications in applied settings. In these instances, every effort should be made to ensure that the predictors are as reliable as possible for selection purposes.

Concerns in Applied Selection

In applied purposes, researchers are often interested not only in the criterion validity of a specific predictor (which is indexed by the appropriate effect size) but also in predicting scores on the criterion variable of interest. For a single predictor, this is done with the following equation:

$$y_i = b_0 + b_1x_i, \quad (1)$$

where y_i is the score on the criterion variable for person i , x_i is the score on the predictor variable for person i , b_0 is the intercept for the regression model, and b_1 is the slope for predictor x . Equation 1 allows the researcher to predict scores on the criterion variable from scores on the predictor variable. This can be especially useful when a researcher wants the performance of selected employees to meet a minimum threshold.

When multiple predictors are employed, the effect size of interest is not any single bivariate correlation but the multiple correlation between a set of predictors and a single criterion of interest (which might be indexed with the multiple R or R^2 from a regression model). In these instances, the prediction equation analogous to Equation 1 is

$$y_i = b_0 + b_{1x1i} + b_{2x2i} + \dots + b_{px_{pi}}, \quad (2)$$

where $x_{1i}, x_{2i}, \dots, x_{pi}$ are the scores on the predictor variables 1, 2, $\dots$, p for person i , $b_1, b_2, \dots, b_p$ are the slopes for predictors $x_1, x_2, \dots, x_p$, and other terms are as defined earlier. Equation 2 allows the researcher to predict scores on a criterion variable given scores on a set of p predictor variables.

Predictive Bias

A unique situation arises in applied selection situations because of federal guidelines requiring criterion validity evidence for predictors that show adverse impact between *protected groups*. Protected groups include (but are not limited to) ethnicity, gender, and age. Adverse impact arises when applicants from one protected group (e.g., males) are selected at a higher rate than members from another protected group (e.g., females). Oftentimes, adverse impact arises because of substantial group differences on the predictor on which applicants are being selected. In these instances, the focal predictor must be shown to exhibit criterion validity across all people being selected. However, it is also useful to examine predictive bias.

For the sake of simplicity, predictive bias will be explicated here only in the case of a single predictor, though the concepts can certainly be extended to the case of multiple predictors. In order to examine the predictive bias of a criterion validity estimate for a specific predictor, it is assumed that the variable on which bias is assessed is categorical; examples would include gender or ethnicity. The appropriate equation would be

$$y_i = b_0 + b_{1x1i} + b_{2x2i} + b_3(x_{1i} * x_{2i}), \quad (3)$$

where x_{1i} and x_{2i} are the scores on the continuous predictor variable and the categorical demographic variable, respectively, for person i , b_1 is the regression

coefficient for the continuous predictor, b_2 is the regression coefficient for the categorical predictor, b_3 is the regression coefficient for the interaction term, and other terms are defined as earlier. Equation 3 has substantial implications for bias in criterion validity estimates. Assuming the reference group for the categorical variable (e.g., males) is coded as 0 and the focal group (e.g., females) is coded as 1, the b_0 coefficient gives the intercept for the reference group, and the b_1 coefficient gives the regression slope for the reference group. These two coefficients form the baseline of criterion validity evidence for a given predictor. The b_2 coefficient and the b_3 coefficient give estimates of how the intercept and slope estimates, respectively, change for the focal group.

The b_2 and b_3 coefficients have strong implications for bias in criterion validity estimates. If the b_3 coefficient is large and positive (negative), then the slope differences (and criterion validity estimates) are substantially larger (smaller) for the focal group. However, if the b_3 coefficient is near zero, then the criterion validity estimates are approximately equal for the focal and reference groups. The magnitude of the b_2 coefficient determines (along with the magnitude of the b_3 coefficient) whether the criterion scores are over- or underestimated for the focal or reference groups depending on their scores on the predictor variable. It is generally accepted that for predictor variables with similar levels of criterion validity, those exhibiting less predictive bias should be preferred over those exhibiting more predictive bias. However, there is some room for trade-offs between criterion validity and predictive bias.

CRITERION VARIABLE

Criterion variable is a name used to describe the dependent variable in a variety of statistical modeling contexts, including multiple regression, discriminant analysis, and canonical correlation. The goal of much statistical modeling is to investigate the relationship between a (set of) criterion variable(s) and a set of predictor variables. The outcomes of such analyses are myriad and include as possibilities the development of model formulas, prediction rules, and classification rules. Criterion variables are also known under a number of other names, such as *dependent variable*, *response variable*, *predictand*, and *Y*. Similarly, predictor variables are often referred to using names such as independent variable, explanatory variable, and *X*. While such names are suggestive of a cause-and-effect relationship between the predictors and the criterion variable(s), great care should be taken in assessing causality. In general, statistical modeling alone does not establish a causal relationship between the variables but rather reveals the existence or otherwise of an observed association, where changes in the predictors are concomitant, whether causally or not, with changes in the criterion variable(s). The determination of causation typically requires further investigation, ruling out the involvement of confounding variables (other variables that affect both explanatory and criterion variables, leading to a significant association between them), and, often, scientifically explaining the process that gives rise to the causation. Causation can be particularly difficult to assess in the context of observational studies (experiments in which both explanatory and criterion variables are observed). In designed experiments, where, for example, the values of the explanatory variables might be fixed at particular, pre-chosen levels, it may be possible to assess causation more effectively as the research design more readily permits the adjustment of certain explanatory variables

in isolation from the others, allowing a clearer judgment to be made about the nature of the relationship between the response and predictors. This entry's focus is on types of criterion variables and analysis involving criterion variables.

Types of Criterion Variables

Criterion variables can be of several types, depending on the nature of the analysis being attempted. In many cases, the criterion variable is a measurement on a continuous or interval scale. This case is typical in observational studies, in which the criterion variable is often the variable of most interest among a large group of measured variables that might be used as predictors. In other cases, the criterion variable may be discrete, either ordinal (ordered categories) or nominal (unordered categories). A particularly important case is that of a binary (0/1) criterion variable, for which a common modeling choice is the use of logistic regression to predict the probability of each of the two possible outcomes on the basis of the values of the explanatory variables. Similarly, a categorical criterion variable requires particular modeling choices, such as multinomial logistic regression, to accommodate the form of the response variable. Increasingly, flexible nonparametric methods such as classification trees are being used to deal with categorical or binary responses, the strength of such methods being their ability to effectively model the data without the need for restrictive classical assumptions such as normality.

Types of Analysis Involving Criterion Variables

The types of analysis that can be used to describe the behavior of criterion variables in relation to a set of explanatory variables are likewise broad. In a standard regression context, the criterion variable is modeled as a (usually) linear function of the set of explanatory variables. In its simplest form, linear regression also assumes zero-mean, additive, homoscedastic errors. *Generalized linear models* extend simple linear regression by modeling a function (called the *link function*) of the criterion variable in terms of a linear function (called the *linear predictor*) of the explanatory variables. The criterion variable is assumed to arise from an exponential family distribution, the type of which leads to a canonical link function, the function for which $X^T Y$ is a sufficient statistic for β , the vector of regression coefficients. Common examples of exponential family distributions with their corresponding canonical link function include the *normal* (identity link), *poisson* (log link), *binomial* and *multinomial* (logit link), and

exponential and gamma (inverse link) distributions. Generalized linear models allow for very flexible modeling of the criterion variable while retaining most of the advantages of simpler parametric models (compact models, easy prediction). Nonparametric models for the criterion variable include methods such as *regression trees*, *projection pursuit*, and *neural nets*. These methods allow for flexible models that do not rely on strict parametric assumptions, although using such models for prediction can prove challenging.

Outside the regression context, in which the goal is to model the value of a criterion variable given the values of the explanatory variables, other types of analysis in which criterion variables play a key role include *discriminant analysis*, wherein the values of the predictor (input) variables are used to assign realizations of the criterion variable into a set of predefined classes based on the values predicted for a set of linear functions of the predictors called *discriminant functions*, through a model fit via data (called the *training set*) for which the correct classes are known.

In *canonical correlation analysis*, there may be several criterion variables and several independent variables, and the goal of the analysis is to reduce the effective dimension of the data while retaining as much of the dependence structure in the data as possible. To this end, linear combinations of the criterion variables and of the independent variables are chosen to maximize the correlation between the two linear combinations. This process is then repeated with new linear combinations as long as there remains significant correlation between the respective linear combinations of criterion and independent variables. This process resembles principal components analysis, the difference being that correlation between sets of independent variables and sets of criterion variables is used as the means of choosing relevant linear combinations rather than the breakdown of variation used in principal components analysis.

Finally, in all the modeling contexts in which criterion variables are used, there exists an asymmetry in the way in which criterion variables are considered compared with the independent variables, even in observational studies, in which both sets of variables are observed or measured as opposed to fixed, as in a designed experiment. Fitting methods and measures of fit used in these contexts are therefore designed with this asymmetry in mind. For example, least squares and misclassification rates are based on deviations of realizations of the criterion variable from the predicted values from the fitted model.

CRITICAL CASE

A critical case usually refers to a single case under investigation that provides so much detail in a context with such great relevance that new theoretical propositions can be created, developed, revised, or debunked. A critical case can build a theory by either disproving an existing theory or by formulating a new one from scratch. In addition, it can serve as a catalyst for further developing an existing theory. Critical case studies are usually qualitative studies.

Leon Festinger's cognitive dissonance theory is a good illustration of how a theory can be built through a critical case. After the magnitude 8 earthquake in India-Nepal in 1934, Festinger observed that affected people in the vicinity of the damaged area were worried about the possibility of worse disasters to follow. Although it seems counterintuitive, their distress was not a sign of future events, but an attempt to accept what had already happened by hyperbolizing the risk of future events so as to reduce the psychological impact of the anxiety brought on by the earthquake. Festinger's observation, instrumental to his case study, led to the emergence of dissonance reduction theory (i.e., fitting one's own worldview with how one thinks and feels).

Single Versus Multiple Case Studies

Critical cases for the revolutionary power they represent are usually single, in the sense that they do not need further confirmation by other cases. Differing from multiple case studies, whereby the researcher comparatively investigates several cases to understand the differences

and the similarities among them, a single critical case provides enough in-depth understanding of the phenomenon that further investigation is only marginal. Thus, the question of generalizability depends on the strategic choice of the case (i.e., case relevance within a context), its meaningful outcomes (i.e., the case insights), and its further implementation (i.e., case replication). In contrast with multiple case studies, here the generalizability does not rely on the volume of the collected data.

The Critical Case as an Innovation

A parallelism can be drawn between a critical case and an innovation, whereby the researcher is depicted as an entrepreneur. Through the power of creativity, the researcher perceives an opportunity to transform the status quo of a defined phenomenon. Like a Schumpeterian, he tries to destroy the *old* (scheme or theory) for creating the *new* (e.g., approach, theory, principle). Like a Popperian, the observer aims to falsify the present for creating the future and, like a Kuhnian, aims to invent new paradigms for shifting the focus toward novel theoretical propositions or to reject or falsify current ones. In doing so, the researcher navigates across chaos and complexity (i.e., the road to invention) up to a relative and temporary certainty (i.e., the invention). The latter is relativized by new falsifiability attempts by the same researcher or others. Essentially, when the critical case creates a new theory, with or without debunking an existing one, then this is similar to a *radical* innovation (e.g., Galileo's law of gravity). When the critical case improves or develops an existing theory, then this is like an *incremental* innovation (e.g., Newtonian mechanics as a development of Galileo's perspective).

Methodological Aspects of Single Case Research

Critical cases rely primarily on qualitative methodology, exploratory design, and nonrandom sampling. The case is chosen because of a particular (intrinsic) interest, not as a representative sample of a larger population. Qualitative data are obtained through interviews, direct and participant observations, and archives. To construct validity, it is important to triangulate multiple sources of data. Based on case design and theoretical contribution, single case studies can be classified as theory building or theory development. The theory-building process starts with a genuine interest in the phenomenon without relying on previous theoretical constructs. Thus, the case itself reflects the intrinsic interest of the researcher who behaves as an observer of general aspects around the phenomenon under investigation. Since the phenomenon is new, general descriptions are aggregated with

qualitative data obtained through interviews, documents' analysis, and further observations. As a result, like a radical innovation, new theoretic-based constructs and relationships emerge. The theory-development process starts from an existing theory and aims to extend and improve it, like an incremental innovation. The phenomenon is partially understood, but there is space for improvement. Consequently, the current antecedents and outcomes of the existing theory are reconsidered and refined in order to build new theoretical constructs. Thus, an attempted theory emerges as an improved version of the previous existing theory.

Generalizing From a Single Critical Case

A concern some scholars raise about single critical cases is related to the belief that critical cases cannot be generalized due to contestable generalizations. Following this view, cases can be just the starting point of a long research path but must be complemented with other research methods. In contrast, other scholars believe that with a case study approach, generalizability is not about the amount of data but about the *amount* of logical reasoning. For example, to falsify the statement that "all towers are straight," it is sufficient to observe an inclined one (e.g., the Leaning Tower of Pisa). Just one observation of a single leaning tower would falsify the aforementioned proposition, providing at the same time a general significance while stimulating further investigations and theory building. Consequently, concrete cases and examples could be just as valuable as generic rules or statistical generalization. Hence, the interpretivist paradigm enables the researcher to derive from a single critical case the following: concepts, theory, implications, and insights. For example, many business concepts and terminology originate from single business practices or cases (e.g., just in time, management by objectives, blue ocean strategy, disruptive innovation, knowledge worker).

CRITICAL DIFFERENCE

A critical difference (which is analogous to the *margin of error* in sampling) is the smallest difference between two estimates (or an estimate and a value) beyond which statistical significance may be inferred. Critical regions comprise these rejection regions, beyond the critical differences, for a priori and post hoc comparisons of pairs of means and of linear combinations of means. Critical differences can be transformed into confidence intervals by adding and subtracting this value to the point estimate. First, this entry discusses critical differences in the context of multiple comparison tests for means. Second, this entry addresses confusion surrounding applying critical differences for statistical significance and for the special case of consequential or practical significance.

Means Model

Multiple comparison tests arise from parametric and nonparametric tests of means, medians, and ranks corresponding to different groups. The parametric case for modeling means can be described as $y_{ij} = \mu_i + \varepsilon_{ij}$, which often assumes $\varepsilon_{ij} \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$,

where $i = 1 \dots p$ (number of treatments) and $j = 1 \dots n_i$ (sample size of the i th treatment). The null hypothesis is that all of the means are equal:

$$H_0 = \mu_1 = \mu_2 = \dots = \mu_p,$$

$$H_A : \mu_i \neq \mu_j; i \neq j,$$

and the appropriate test is an F test. Regardless of the result of this test, a priori tests are always considered. However, post hoc tests are considered only if the F test is significant. That is, there are at least two means that are significantly different. Both a priori and post hoc tests compare means and/or linear combinations of means. Comparing means is a natural follow-up after

rejecting $H_0 : \mu_1 = \mu_2 = \dots = \mu_p$, to infer which pairs of means are different.

Multiple Comparison Tests for Means

Multiple comparison tests serve to uncover which pairs of means or linear contrasts of means are significantly different. They are often applied to analyze the results of an experiment. When the null hypothesis is that all means are equal, it is natural to compare pairs of means:

$$H_0 : \mu_i = \mu_j,$$

$$H_A : \mu_i \neq \mu_j; i \neq j.$$

The straightforward comparison of the two means can be generalized to a linear contrast:

$$H_0 : \sum c_i \mu_i = 0,$$

$$H_A : \sum c_i \mu_i \neq 0.$$

Linear contrasts describe testing other combinations of means. For example, the researcher might test whether the third treatment mean in an experiment is different from the average of the first and second treatment means, $\mu_3 \neq (\mu_1 + \mu_2) / 2$. This can be expressed as

$$H_0 : \mu_3 - \frac{1}{2}\mu_1 - \frac{1}{2}\mu_2 = 0,$$

$$H_A : \mu_3 - \frac{1}{2}\mu_1 - \frac{1}{2}\mu_2 \neq 0.$$

Table 1 contains equations describing critical differences corresponding to typical multiple comparison tests. The first term (often called a *critical value*) is a distance in terms of standard errors for the comparison, and the second term is an estimate of that standard error. The number of treatments is denoted by p ; k is the number of comparisons; the i th treatment group contains n_i observations; $N = \sum n_i$ denotes the total number of observations in the experiment; α denotes the experimentwise error rate (this is sometimes an upper bound and cannot always be calculated exactly); and $\alpha_k = 1 - (1 - \alpha)^{k-1}$. The comparisonwise error rate refers to the error rate for all of the comparisons, and the experimentwise error rate refers to the error rate for the entire experiment. The degrees of freedom used in the table, $N - p$, are for a one-way treatment structure. This list is not exhaustive and is intended to be illustrative only. Many of the critical differences have variations. These same critical differences can be used for constructing confidence intervals. However, caution is warranted as the intervals might not be efficient. In addition to means, there are nonparametric critical differences for medians and for ranks.

Table I Critical Difference Examples

Test	Paired Comparisons $H_0 : \mu_i = \mu_j$ $H_A : \mu_i \neq \mu_j; i \neq j$	Critical Differences For Contrasts $H_0 : \sum c_i \mu_i = 0$ $H_A : \sum c_i \mu_i \neq 0$
Bonferroni's	$t_{\alpha/2k, N-p} \hat{\sigma} \sqrt{\frac{1}{n_i} + \frac{1}{n_j}}$	$t_{\alpha/2k, N-p} \hat{\sigma} \sqrt{\sum \frac{c_i^2}{n_i}}$
Duncan's method ($n_i = n_j$)	Comparing the order statistics of the means: $q(\alpha, p, N-p) \frac{\hat{\sigma}}{\sqrt{n}}$	Designed for pairwise comparisons of order statistics.
Duncan's method ($n_i \cong n_j$)	Comparing the order statistics of the means: $q(\alpha, p, N-p) \frac{\hat{\sigma}}{\sqrt{p \left(\frac{1}{n_1} + \frac{1}{n_2} + \dots + \frac{1}{n_p} \right)^{-1}}}$	Designed for pairwise comparisons of order statistics.
Fisher's LSD	$t_{\alpha/2, N-p} \hat{\sigma} \sqrt{\frac{1}{n_i} + \frac{1}{n_j}}$	$t_{\alpha/2, N-p} \hat{\sigma} \sqrt{\sum \frac{c_i^2}{n_i}}$
Multivariate t method	$t_{\alpha/2, k, N-p} \hat{\sigma} \sqrt{\frac{1}{n_i} + \frac{1}{n_j}}$	$t_{\alpha/2, k, N-p} \hat{\sigma} \sqrt{\sum \frac{c_i^2}{n_i}}$
Newman-Keuls' ($n_i = n_j$)	Comparing the order statistics of the means: $q(\alpha, p, N-p) \frac{\hat{\sigma}}{\sqrt{n}}$	Designed for pairwise comparisons of order statistics.
Newman-Keuls' ($n_i \cong n_j$)	Comparing the order statistics of the means: $q(\alpha, p, N-p) \frac{\hat{\sigma}}{\sqrt{p \left(\frac{1}{n_1} + \frac{1}{n_2} + \dots + \frac{1}{n_p} \right)^{-1}}}$	Designed for pairwise comparisons of order statistics.
Scheffe's	$\sqrt{(p-1)F_{\alpha, p-1, N-p}} \hat{\sigma} \sqrt{\frac{1}{n_i} + \frac{1}{n_j}}$	$\sqrt{(p-1)F_{\alpha, p-1, N-p}} \hat{\sigma} \sqrt{\sum \frac{c_i^2}{n_i}}$
Tukey's ($n_i = n_j$)	$q(\alpha, p, N-p) \frac{\hat{\sigma}}{\sqrt{n}}$	$q(\alpha, p, N-p) \frac{\hat{\sigma}}{\sqrt{n}} \left(\frac{1}{2} \sum c_i \right)$
Tukey's ($n_i \cong n_j$)	$q(\alpha, p, N-p) \frac{\hat{\sigma}}{\text{MIN}(\sqrt{n_i}, \sqrt{n_j})}$	$q(\alpha, p, N-p) \frac{\hat{\sigma} \left(\frac{1}{2} \sum c_i \right)}{\text{MIN}(\sqrt{n_i}, \sqrt{n_j})}$

Consequential or Practical Significance and the Two Classic Schools

Multiple comparison tests are designed to reveal statistical significance. Sometimes the researcher's objective is to find consequential significance, which is a special case of statistical significance. Finding statistical significance between two means indicates that they are discernible at a given level of significance, α . *Consequential significance* indicates that they are discernible, and the magnitude of the difference is large enough to generate consequences. The corresponding confusion is pandemic. To adjust the critical differences to meet the needs of consequential significance, an extra step is wanted.

There are two classic statistical schools:

- (1) Fisher (Fisherian): This school does not need an alternative hypothesis.
- (2) Neyman–Pearson: This school insists on an alternative hypothesis:

$$H_0 : \mu_1 - \mu_2 = 0,$$

$$H_A : \mu_1 - \mu_2 \neq 0.$$

Ronald A. Fisher was the first to address the matter of hypothesis testing. He defined statistical significance to address the need for discerning between two treatments. His school emphasizes discerning whether one treatment mean is greater than the other, without regard to the magnitude of the difference. This approach is in keeping with the usual critical differences as illustrated in Table 1. They pronounce whether any difference between the means is discernible and whether the ordering is statistically reliable.

Jerzy Neyman would say that the alternative hypothesis, H_A , should represent the consequential scenario. For example, suppose that if the mean of Treatment 1 exceeds the mean of Treatment 2 by at least some amount c , then changing from Treatment 2 to Treatment 1 is consequential. The hypotheses might take the following form:

$$H_0 : \mu_1 - \mu_2 - c = 0,$$

$$H_A : \mu_1 - \mu_2 - c > 0,$$

where c is the consequential difference. For detecting consequential significance using a multiple comparison test, the final step consists of adding or multiplying by constants, which should be derived from economic or scientific calculations—from the problem. In the application and instruction of statistics, the two classic schools are blended, which sows even more confusion.

CRITICAL THEORY

A theory consists of a belief or beliefs that allow researchers to examine and analyze the world around them. This entry examines critical theory and how critical ideas can be applied to research. As Peter Barry suggests, we can use theory rather than theory's using us. The complexity of any theory, let alone the critical theories examined in this entry, cannot be underestimated, but theory can be used to produce better research methodology and also to test research data. Theory is important because it allows us to question our beliefs, meanings, and understandings of the world around us. In all subject areas, critical theory provides a multidimensional and wide-ranging critique of research problems that researchers attempt to address. The importance of how we read, apply, and interpret critical theories is crucial within any research design. Within this entry, the aim is to increase understandings of Marxism, critical race theory, postmodernism, and poststructuralism and also to show, through the evidence bases of literature and reflective experiences, how critical theories can be used by the researcher within different parts of research design.

Marxist Critique

Marx's critique of the free market economy and capitalism is as applicable today as it was in the 19th century. Capitalism as an ideology was a power structure based on exploitation of the working classes. Economic production revolves around the exploited relationship

between bourgeoisie and proletariat. The bourgeoisie have monopolized production since the beginning of the industrial revolution, forcing the proletariat from the land and into structured environments (e.g., urban factories). Peasants became workers, and the working wage was a controlled, structured device that gives the proletariat only a fraction of the generated revenue. The surplus value from production is a profit that is taken by the bourgeoisie. Critical theorists would argue that this practice is both theft and wage slavery. This leads to wider consequences (i.e., overproduction), which in the 20th and 21st centuries has had wide implications for the environment. Marxism favors social organization with all individuals having the right to participate in consumption and production. The result of class exploitation, Marxists believe, would be the revolutionary overthrow of capitalism with communism.

Max Horkheimer, a founding member of the Frankfurt School in the 1920s and 1930s, wanted to develop critical theory as a form of Marxism, with the objective of changing society. His ideas attempted to address the threat not only of fascism in Europe but of the rise of consumer culture, which can create forms of cultural hegemony and new forms of social control. Theory adapts to changing times, but within new social situations, theories can be developed and applied to contemporary contexts. Horkheimer's focus on consumer culture can be used today within modern communication when we reflect on how people today socialize. One example is Facebook and the ways behavioral patterns continue to change as people use the World Wide Web more and more to exchange personal information. What are the consequences of these changes for social organization and consumer culture?

A very contemporary application of Marxism has been provided by Mike Cole, who applies Marxist ideas to education by using the example of Venezuela and Hugo Chávez, who opposed Capitalism and imperialism. In education, Cole highlights, Chávez had hoped to open 38 new state universities with 190 satellite classrooms throughout Venezuela by 2009. Social projects such as housing are linked to this policy. Communal councils have been created whereby the local population meets to decide on local policies and how to implement them, rather than relying on bourgeois administrative machinery. Chávez was not only talking about democratic socialism but applying it to government policy. Therefore, one can apply Marxist critique politically in different parts of the world. Chávez's policies are a reaction to capitalism and the colonial legacy and have the objective of moving Venezuela in a more socialist direction. Application and interpretation are

the keys when applying critical theory within research design. Cole applies Marxist ideas to the example of Venezuela and provides evidence to interpret the events that are taking place. Critical theory can be effective when it is applied in contemporary contexts.

Critical Race Theory

The critical race theory (CRT) movement is a collection of activists and scholars interested in studying and transforming the relationship among race, racism, and power. Although CRT began as a movement in the United States within the subject of law, it has rapidly spread beyond that discipline. Today, academics in the social and behavioral sciences, including the field of education, consider themselves critical race theorists who use CRT ideas to, according to Richard Delgado and Jean Stefancic, understand issues of school discipline, controversies, tracking, and IQ and achievement testing. CRT tries not only to understand our social situation but to change it. The focus of CRT is racism and how it is socially and culturally constructed. CRT goes beyond a conceptual focus of multiculturalism, which examines equal opportunities, equity, and cultural diversity. Barry Troyna carried out education research in the United Kingdom during the 1970s and 1980s with an antiracist conceptual analysis, arguing that multiculturalism did not focus on antiracist practice enough. CRT has that central focus and goes further in relation to how minority groups are racialized and colored voices silenced. CRT offers everyone a voice to explore, examine, debate, and increase understandings of racism. David Gillborn is an advocate of applying CRT within research, explaining that the focus of CRT is an understanding that the status of Black and other minority groups is always conditional on Whites. As Gillborn highlights, to many Whites, such an analysis might seem outrageous, but its perceptiveness was revealed in dramatic fashion in July 2005, with the terrorist attacks on London and Madrid. Gillborn underlines that this was the clearest demonstration of the conditional status of people of color in contemporary England. So power conditions are highlighted by CRT. The application of CRT within research design can be applied in many subject areas and disciplines. That notion of power and how it is created, reinforced, and controlled is an important theme within critical theory.

Postmodernism

Postmodernism also examines power relations and how power is made and reinforced. To understand what postmodernism is, we have to understand what

modernism was. Peter Barry explains that modernism is the name given to the movement that dominated arts and culture in the first half of the 20th century. Practice in music, literature, and architecture was challenged. This movement of redefining modernism as postmodernist can be seen in the changing characteristics of literary modernism. Barry provides a position that concerns literary modernism and the move to postmodernist forms of literature. It can be applied more broadly to research design and the application of critical theory. The move away from grand-narrative social and cultural theories can be seen in the above as philosophers and cultural commentators moved away from “objective” positions and began to examine multiple points of views and diverse moral positions. Postmodernists are skeptical about overall answers to questions that allow no space for debate. Reflexivity allows the researcher to reflect on his or her own identity or identities within a given profession. The idea of moving beyond a simplistic mirror image or “Dear Diary” approach to a reflective method with the application of different evidence bases of literature reviews to personal experiences shows how status, roles, and power can be critically analyzed. The plurality of roles that occurs is also a postmodern development with the critical questioning of the world and the multiple identities that globalization gives the individual. In relation to research design, a postmodern approach gives the researcher more possibilities in attempting to increase understandings of a research area, question, or hypothesis. Fragmented forms, discontinuous narrative, and the random nature of material can give the researcher more areas or issues to examine. This can be problematic as research focus is an important issue in the research process and it is vital for the researcher to stay focused. That last line would immediately be questioned by a postmodernist because the position is one of constant questioning and potential change. The very nature of research and research design could be questioned by the postmodernist. The issue here is the creation and development of ideas, as it is for all researchers. Jean-François Lyotard believed that the researcher and intellectual should resist the grand ideas and narratives that had become, in his opinion, outdated. Applying that directly to research design, a modernist argument would be that the research process should consist of an introduction with a research question or hypothesis; literature review; method and methodology; data collection, presentation, and analysis; and a conclusion. If one were being critical of that provisional research design structure, one could suggest that research questions (plural) should be asked, literature reviews (subject specific, general, theoretical, conceptual, method, data) should be carried out, and all

literature should be criticized; positivist research paradigms should be dropped in favor of more reflective, action research projects; and other questions should be answered rather than the focal question or hypothesis posed at the beginning of the research project. Research design itself would be questioned because that is the very nature of postmodernist thought: the continuing critique of the subject under examination.

Poststructuralism

The issue of power and knowledge creation is also examined within poststructuralism in the sense that this form of critical theory aims to deconstruct the grand narratives and structural theoretical frameworks. Poststructuralism also attempts to increase understandings of language and the ways knowledge and power are used and evolve to shape how we view structures (e.g., the institution in which we work and how it works) and why we and others accept how these structures work. Poststructuralism is critical of these processes and attempts to analyze new and alternative meanings. In relation to research design, it is not only how we apply critical theory to poststructuralist contexts, it is how we attempt to read the theory and theorists. Michel Foucault is a poststructuralist, and his works are useful to read in association with issues of research design. Poststructural ideas can be used to examine the meanings of different words and how different people hold different views or meanings of those words. The plurality of poststructuralist debate has been criticized because considering different or all arguments is only relative when an absolute decision has to be taken. However, it is the question of language and meaning in relation to power and knowledge that offers the researcher a different angle within research design.

Application Within the Social and Behavioral Sciences

This final section highlights how critical theory, be it Marxism, CRT, postmodernism, or poststructuralism, can be applied within the social and behavioral sciences. It is not only the word *application* that needs to be focused on but interpretation and one's interpretations in relation to one's research question or hypothesis. Researchers reading the primary sources of Marx, Foucault, or Lyotard and applying them to a research design is all very well, but interpreting one's own contextual meanings to methodology from the literature reviews and then applying and interpreting again to data analysis seems to be more difficult. Two different meanings could materialize here, which is

due to the fact that space and time needs to be given within research design for reading and rereading critical theories to increase understandings of what is being researched. Critical theories can be described as windows of opportunity in exploring research processes in the social and behavioral sciences. They can be used as a tool within research design to inform, examine, and ultimately test a research question and hypothesis. Critical theoretical frameworks can be used within research introductions, literature reviews, and method and methodology processes. They can have a role to play in data analysis and research conclusions or recommendations at the end of a research project. It is how the researcher uses, applies, and interprets critical theory within research design that is the key issue.

CRITICAL THINKING

Critical thinking evaluates the validity of propositions. It is the hallmark and the cornerstone of science because science is a community that aims to generate true statements about reality. The goals of science can be achieved only by engaging in an evaluation of statements purporting to be true, weeding out the false ones, and limiting the true ones to their proper contexts. Its centrality to the scientific enterprise can be observed in the privileges accorded to critical thinking in scientific discourse. It usually trumps all other considerations, including tact, when it appears in a venue that considers itself to be scientific.

A *proposition* is a statement that claims to be true, a statement that claims to be a good guide to reality. Not all statements that sound as if they may be true

or false function as propositions, so the first step in critical thinking is often to consider whether a proposition is really being advanced. For example, “I knew this was going to happen” is often an effort to save face or to feel some control over an unfortunate event rather than an assertion of foreknowledge, even though it sounds like one. Conversely, a statement may not sound as if it has a truth element, but on inspection, one may be discovered. “Read Shakespeare” may sometimes be translated as the proposition, “Private events are hard to observe directly, so one way to learn more about humans is to observe public representations of private thoughts as described in context by celebrated writers.” Critical thinking must evaluate statements properly stated as propositions; many disagreements are settled simply by ascertaining what, if anything, is being proposed. In research, it is useful to state hypotheses explicitly and to define the terms of the hypotheses in a way that allows all parties to the conversation to understand exactly what is being claimed.

Critical thinking contextualizes propositions; it helps the thinker consider when a proposition is true or false, not just whether it is true or false. If a proposition is always true, then it is either a tautology or a natural law. A *tautology* is a statement that is true by definition: “All ermines are white” is a tautology in places where nonwhite ermines are called weasels. A *natural law* is a proposition that is true in all situations, such as the impossibility of traveling faster than light in a vacuum. The validity of all other propositions depends on the situation. Critical thinking qualifies this validity by specifying the conditions under which they are good guides to reality.

Logic is a method of deriving true statements from other true statements. A *fallacy* occurs when a false statement is derived from a true statement.

This entry discusses methods for examining propositions and describes the obstacles to critical thinking.

Seven Questions

Critical thinking takes forms that have proven effective in evaluating the validity of propositions. Generally, critical thinkers ask, in one form or another, the following seven questions:

1. What does the statement assert? What is asserted by implication?
2. What constitutes evidence for or against the proposition?
3. What is the evidence for the proposition? What is the evidence against it?

4. What other explanations might there be for the evidence?
5. To which circumstances does the proposition apply?
6. Are the circumstances currently of interest like the circumstances to which the proposition applies?
7. What motives might the proponent of the proposition have besides validity?

What Does the Statement Assert? What Is Asserted by Implication?

The proposition *Small schools produce better citizens than large schools do* can be examined as an illustrative example. The first step requires the critical thinker to define the terms of the proposition. In this example, the word *better* needs elaboration, but it is also unclear what is meant by *citizen*. Thus, the proponent may mean that better citizens are those who commit fewer crimes or perhaps those who are on friendly terms with a larger proportion of their communities than most citizens.

Critical thinkers are alert to hidden tautologies, or to avoiding the fallacy of *begging the question*, in which *begging* is a synonym for *pleading* (as in pleading the facts in a legal argument) and *question* means the proposition at stake. It is fallacious to prove something by assuming it. In this example, students at smaller schools are bound to be on speaking terms with a higher proportion of members of the school community than are students at larger schools, so if that is the definition of better citizenship, the proposition can be discarded as trivial. Some questions at stake are so thoroughly embedded in their premises that only very deep critical thinking, called *deconstruction*, can reveal them. Deconstruction asks about implied assumptions of the proposition, especially about unspoken dualities. Thus, a critical thinker would want to examine whether it makes sense to consider one citizen better than another or whether the proposition is implying that schools are responsible for social conduct rather than for academics.

Critical thinkers are also alert to artificial categories. When categories are implied by a proposition, they need to be examined as to whether they really exist. Most people would accept the reality of the category *school* in the contemporary United States, but not all societies have clearly demarcated mandatory institutions where children are sent during the day. It is far from clear that the categories of smaller schools and larger schools stand up to scrutiny, because school populations, though not falling on a smooth curve, are more linear than categorical. The proponent might switch the proposition to *School size predicts later criminal activity*.

What Constitutes Evidence for or Against the Proposition?

Before evidence is evaluated for its effect on validity, it must be challenged by questions that ask whether it is good evidence of anything. This is generally what is meant by reliability. If a study examines a random sample of graduates' criminal records, critical thinkers will ask whether the sample is truly random, whether the available criminal records are accurate and comprehensive, whether the same results would be obtained if the same records were examined on different days by different researchers, and whether the results were correctly transcribed to the research protocols.

It is often said that science relies on evidence rather than on *ipse dixit*, which are propositions accepted solely on the authority of the speaker. This is a mistaken view, because all propositions ultimately rest on *ipse dixit*. In tracking down criminal records, for example, researchers will eventually take someone's—or a computer's—word for something.

What Is the Evidence for the Proposition? What Is the Evidence Against It?

These questions are useful only if they are asked, but frequently people ask only about the evidence on the side they are predisposed to believe. When they do remember to ask, people have a natural tendency, called *confirmation bias*, to value the confirming evidence and to dismiss the contradictory evidence.

Once evidence is adduced for a proposition, one must consider whether the very same evidence may stand against it. For example, once someone has argued that distress in a child at seeing a parent during a stay in foster care is a sign of a bad relationship, it is difficult to use the same distress as a sign that it is a good relationship. But critical thinking requires questioning what the evidence is evidence of.

What Other Explanations Might There Be for the Evidence?

To ensure that an assertion of causality is correct, either one must be able to change all but the causal variable and produce the same result, or one must be able to change only the proposed cause and produce a different result. In practice, especially in the social areas of science, this never happens, because it is extremely difficult to change only one variable and impossible to change all variables except one. Critical thinkers identify variables that changed along with the one under consideration. For example, it is hard to find schools of different sizes that also do not involve communities

with different amounts of wealth, social upheaval, or employment opportunities. Smaller schools may more likely be private schools, which implies greater responsiveness to the families paying the salaries, and it may be that responsiveness and accountability are more important than size per se.

To Which Circumstances Does the Proposition Apply?

If a proposition is accepted as valid, then it is either a law of nature—always true—or else it is true only under certain circumstances. Critical thinkers are careful to specify these circumstances so that the proposition does not become overly generalized. Thus, even if a causal relationship were accepted between school size and future criminality, the applicability of the proposition might have to be constricted to inner cities or to suburbs, or to poor or rich schools, or to schools where entering test scores were above or below a certain range.

Are the Circumstances Currently of Interest Like the Circumstances to Which the Proposition Applies?

Once a proposition has been validated for a particular set of circumstances, the critical thinker examines the current situation to determine whether it is sufficiently like the validating circumstances to apply the proposition to it. In the social sciences, there are always aspects of the present case that make it different from the validating circumstances. Whether these aspects are different enough to invalidate the proposition is a matter of judgment. For example, the proposition relating school size to future criminality could have been validated in California, but it is unclear whether it can be applied to Texas. Critical thinkers form opinions about the similarity or differences between situations after considering reasons to think the current case is different from or similar to the typical case.

What Motives Might the Proponent of the Proposition Have Besides Validity?

The scientific community often prides itself on considering the content of an argument rather than its source, purporting to disdain *ad hominem* arguments (those being arguments against the proponent rather than against the proposition). However, once it is understood that all evidence ultimately rests on *ipse dixit*, it becomes relevant to understand the motivations of the proponent. Also, critical thinkers budget their time to examine relevant propositions, so a shocking idea from a novice or an amateur or, especially, an

interested party is not always worth examining. Thus, if a superintendent asserts that large schools lead to greater criminality, one would want to know what this official's budgetary stake was in the argument. Also, this step leads the critical thinker full circle, back to the question of what is actually being asserted. If a high school student says that large schools increase criminality, he may really be asking to transfer to a small school, a request that may not depend on the validity of the proposition.

Thus, critical thinkers ask who is making the assertion, what is at stake for the speaker, from what position the speaker is speaking, and under what conditions or constraints, to what audience, and with what kind of language. There may be no clear or definitive answers to these questions; however, the process of asking is one that actively engages the thinking person in the evaluation of any proposition as a communication.

The Role of Theory

When critical thinkers question what constitutes good evidence, or whether the current situation is like or unlike the validating circumstances, or what motives the proponent may have, how do they know which factors to consider? When they ask about other explanations, where do other explanations come from? Theory, in the sense of a narrative that describes reality, provides these factors and explanations. To use any theorist's theory to address any of these issues is to ask what the theorist would say about them.

Multiculturalism

Multiculturalism provides another set of questions to examine the validity of and especially to constrict the application of a proposition. Someone thinking of large suburban high schools and small suburban parochial schools may think that the proposition relating school size to criminality stands apart from race, sex, and ethnicity. Multicultural awareness reminds us to ask whether these factors matter.

Obstacles to Critical Thinking

If critical thinking is such a useful process for getting at the truth, for producing knowledge that may more efficiently and productively guide our behavior—if it is superior to unquestioning acceptance of popular precepts, common sense, gut instinct, religious faith, or folk wisdom—then why is it not more widespread? Why do some people resist or reject critical thinking? There are several reasons that it can be upsetting. Critical thinkers confront at least six obstacles: losing face,

losing faith, losing friends, thinking the unthinkable, challenging beliefs, and challenging believing.

Losing Face

Critical thinking can cause people to lose face. In nonscientific communities, that is, in communities not devoted to generating true statements about reality, propositions are typically met with a certain amount of tact. It can be awkward to question someone's assertions about reality, and downright rude to challenge their assertions about themselves. When people say something is true and it turns out not to be true, or not to be always true, they lose face. Scientists try to overcome this loss of face by providing a method of saving face, namely, by making a virtue of self-correction and putting truth ahead of pride. But without a commitment to science's values, critical thinking can lead to hurt feelings.

Losing Faith

Religious faith is often expressed in spiritual and moral terms, but sometimes it is also expressed in factual terms—faith that certain events happened at a certain time or that the laws of nature are sometimes transcended. When religion takes a factual turn, critical thinking can oppose it, and people can feel torn between religion and science. Galileo said that faith should concern itself with how to go to heaven, and not with how the heavens go. When people have faith in how reality works, critical thinking can become the adversary of faith.

Losing Friends

Human beings are social; we live together according to unspoken and spoken agreements, and our social networks frequently become communities of practice wherein we express our experiences and observations in terms that are agreeable to and accepted by our friends and immediate communities. Among our intimates and within our social hierarchies, we validate each other's views of reality and find such validation comforting. We embed ourselves in like-minded communities, where views that challenge our own are rarely advanced, and when they are, they and their proponents are marginalized—labeled silly, dangerous, crazy, or unreasonable—but not seriously considered. This response to unfamiliar or disquieting propositions strengthens our status as members of the ingroup and differentiates us from the outgroup. Like-minded communities provide reassurance, and critical thinking—which looks with a curious, analytical, and fearless eye

on propositions—threatens not only one's worldview but one's social ties.

Thinking the Unthinkable

Some of the questions that critical thinkers ask in order to evaluate propositions require an imaginative wondering about alternatives: Would the meaning of evidence change if something about the context changed, could there be some other, unthought-of factor accounting for evidence, or could the evidence itself be suspect? Critical thinking involves considering alternatives that may be banned from discourse because they challenge the status quo or because they challenge the complacency of the thinker. It may not be tolerable to ask whether race matters, for example, in trying to understand any links between school size and criminality, and it may not be tolerable to ask how a group of professionals would behave if arrested, if one is evaluating the proposition that a suspect's behavior on arrest signifies guilt or innocence. Critical thinking can be frightening to people who just want to be left alone and do not want to think about alternatives.

Challenging Beliefs

It is useful for most people to have several central tenets about reality and the human condition that guide their behavior. If anxiety is the feeling of not knowing what to do, it can be comforting to have some beliefs that dictate how to behave. Very few beliefs emerge from the process of critical thinking unchanged and unqualified. The basic propositions on which an individual relies come to seem temporary and situational rather than fundamental and reliable. The result can be an anxious sense that the map being used to navigate reality is out of date or drawn incorrectly. To preserve the security of knowing what to do, many people avoid evaluating their maps and beliefs.

Challenging Believing

The very process of examining beliefs can make them seem arbitrary, like tentative propositions reflecting communicative circumstances and personal motives rather than truisms about reality etched in stone. This happens because critical thinking casts beliefs as statements, as sentences uttered or written by a speaker, and the process of questioning them makes it clear that there are almost always situational and motivational issues to consider. Critical thinking shows us the extent to which our understandings are socially constructed and communicative. With very few exceptions, science's propositions are continually

revised and circumscribed, facts blur with opinions, and our categories turn out to be arbitrary or even in the service of some social agenda. A postmodern world, energized by critical thinking about the key-stones of our beliefs, can be a difficult world to live in for people seeking certainty.

It is the nature of powerful subsystems to preserve their power by setting their definitions of situations in stone, and it is the task of critical thinkers to cast those definitions as revisable, circumscribable, and often-times arbitrary. If truth liberates people from other people's self-serving views of reality, critical thinking is an engine for freedom as well as for truth.

CRITICAL VALUE

The critical value (CV) is used in significance testing to establish the critical and noncritical regions of a distribution. If the test value or statistic falls within the range of the *critical region* (the *region of rejection*), then there is a significant difference or association; thus, the null hypothesis should be rejected. Conversely, if the test value or statistic falls within the range of the *noncritical region* (also known as the *nonrejection region*), then the difference or association is possibly due to chance; thus, the null hypothesis should be accepted.

When using a one-tailed test (either left-tailed or right-tailed), the CV will be on either the left or the right side of the mean. Whether the CV is on the left or right side of the mean is dependent on the conditions of an alternative hypothesis. For example, a scientist might be interested in increasing the average life span

of a fruit fly; therefore, the alternative hypothesis might be $H_1: \mu > 40$ days. Subsequently, the CV is on the right side of the mean. Likewise, the null hypothesis would be rejected only if the sample mean is greater than 40 days. This example would be referred to as a one-tailed right test.

To use the CV to determine the significance of a statistic, the researcher must state the null and alternative hypotheses; set the level of significance, or alpha level, at which the null hypothesis will be rejected; and compute the test value (and the corresponding degrees of freedom, or *df*, if necessary). The investigator can then use that information to select the CV from a table (or calculation) for the appropriate test and compare it to the statistic. The statistical test the researcher chooses to use (e.g., *z*-score test, *z* test, single sample *t* test, independent samples *t* test, dependent samples *t* test, one-way analysis of variance, Pearson product-moment correlation coefficient, chi-square) determines which table he or she will reference to obtain the appropriate CV (e.g., *z*-distribution table, *t*-distribution table, *F*-distribution table, Pearson's table, chi-square distribution table). These tables are often included in the appendixes of introductory statistics textbooks.

For the following examples, the Pearson's table, which gives the CVs for determining whether a Pearson product-moment correlation (*r*) is statistically significant, is used. Using an alpha level of .05 for a two-tailed test, with a sample size of 12 (*df* = 10), the CV is .576. In other words, for a correlation to be statistically significant at the .05 significance level using a two-tailed test for a sample size of 12, then the absolute value of Pearson's *r* must be greater than or equal to .576. Using a significance level of .05 for a one-tailed test, with a sample size of 12 (*df* = 10), the CV is .497. Thus, for a correlation to be statistically significant at the .05 level using a one-tailed test for a sample size of 12, then the absolute value of Pearson's *r* must be greater than or equal to .497.

When using a statistical table to reference a CV, it is sometimes necessary to interpolate, or estimate values, between CVs in a table because such tables are not exhaustive lists of CVs. For the following example, the *t*-distribution table is used. Assume that we want to find the critical *t* value that corresponds to 42 *df* using a significance level or alpha of .05 for a two-tailed test. The table has CVs only for 40 *df* (CV = 2.021) and 50 *df* (CV = 2.009). In order to calculate the desired CV, we must first find the distance between the two known *dfs* (50 – 40 = 10). Then we find the distance between the desired *df* and the lower known *df* (42 – 40 = 2). Next, we calculate the proportion of the distance that the desired *df* falls from the lower known *df* ($\frac{2}{10} = .20$).

Then we find the distance between the CVs for 40 *df* and 50 *df* ($2.021 - 2.009 = .012$). The desired CV is .20 of the distance between 2.021 and 2.009 ($.20 \times .012 = .0024$). Since the CVs decrease as the *dfs* increase, we subtract .0024 from CV for 40 *df* ($2.021 - .0024 = 2.0186$); therefore, the CV for 42 *df* with an alpha of .05 for a two-tailed test is $t = 2.0186$.

Typically individuals do not need to reference statistical tables because statistical software packages, such as SPSS, an IBM company, formerly called PASW Statistics, indicate in the output whether a test value is significant and the level of significance. Furthermore, the computer calculations are more accurate and precise than the information presented in statistical tables.

CROSSOVER DESIGN

There are many different types of experimental designs for different study scenarios. Crossover design is a special design in which each experimental unit receives a sequence of experimental treatments. In practice, it is not necessary that all permutations of all treatments be

used. Researchers also call it *switchover design*, compared with a *parallel group design*, in which some experimental units only get a specific treatment and other experimental units get another treatment. In fact, the crossover design is a specific type of repeated measures experimental design. In the traditional repeated measures experiment, the experimental units, which are applied to one treatment (or one treatment combination) throughout the whole experiment, are measured more than one time, resulting in correlations between the measurements. The difference between crossover design and traditional repeated measures design is that in crossover design, the treatment applied to an experimental unit for a specific time continues until the experimental unit receives all treatments. Some experimental units may be given the same treatment in two or more successive periods, according to the needs of the research.

The following example illustrates the display of the crossover design. Researchers altered the diet ingredients of 18 steers in order to study the digestibility of feedstuffs in beef cattle. There were three treatments, or feed mixes, each with a different mix of alfalfa, straw, and so on. A three-period treatment was used, with three beef steers assigned to each of the six treatment sequences. Each diet in each sequence was fed for 30 days. There was a 21-day washout between each treatment period of the study. Assume that the dependent variable is the neutral detergent fiber digestion coefficient calculated for each steer. For this case, there are three treatment periods and $3! = 6$ different sequences. The basic layout may be displayed as in Table 1.

Table 1 Six-Order Sequence Crossover Table

Sequence	Units	Period 1	Period 2	Period 3
1	1,2,3	A	B	C
2	4,5,6	B	C	A
3	7,8,9	C	A	B
4	10,11,12	A	C	B
5	13,14,15	B	A	C
6	16,17,18	C	B	A

Basic Conceptions, Advantages, and Disadvantages

Crossover designs were first used in agriculture research in 1950s and are widely used in other scientific fields with human beings and animals. The feature that measurements are obtained on different treatments from

each experimental unit distinguishes the crossover design from other experimental designs.

This feature entails several advantages and disadvantages. One advantage is reduced costs and resources when money and the number of experimental units available for the study are limited. The main advantage of crossover design is that the treatments are compared within subjects. The crossover design is able to remove the subject effect from the comparison. That is, the crossover design removes any component from the treatment comparisons that is related to the differences between the subjects. In clinical trials, it is common that the variability of measurements obtained from different subjects is much greater than the variability of repeated measurement obtained from the same subjects.

A disadvantage of crossover design is that it may bring a *carryover effect*, that is, the effect of a treatment given in one period may influence the effect of the treatment in the following period(s). Typically the subjects (experimental units) are given sufficient time to “wash out” the effect of the treatments between two periods in crossover designs and return to their original state. It is important in a crossover study that the underlying condition does not change over time and that the effects of one treatment disappear before the next is applied. In practice, even if sufficient wash-out time is administered after two successive treatment periods, the subjects’ physiological states may have been changed and may be unable to return to the original state, which may affect the effects of the treatment in the succeeding period. Thus, the carryover effect cannot be ignored in crossover designs. In spite of its advantages, the crossover design should not be used in clinical trials in which a treatment cures a disease and no underlying condition remains for the next treatment period. Crossover designs are typically used for persistent conditions that are unlikely to change over the course of the study. The carryover effect can cause problems with data analysis and interpretation of results in a crossover design. The carryover prevents the investigators from determining whether the significant effect is truly due to a direct treatment effect or whether it is a residual effect of other treatments. In multiple regressions, the carryover effect often leads to multicollinearity, which leads to erroneous interpretation. If the crossover design is used and a carryover effect exists, a design should be used in which the carryover effect will not be confounded with the period and treatment effects. The carryover effect makes the design less efficient and more time-consuming.

The *period effect* occurs in crossover design because of the conditions that are present at the time the observed values are taken. These conditions

systematically affect all responses that are taken during that time, regardless of the treatment or the subject. For example, the subjects need to spend several hours to complete all the treatments in sequence. The subjects may become fatigued over time. The fatigue factor may tend to systematically impact all the treatment effects of all the subjects, and the researcher cannot control this situation. If the subject is diseased during the first period, regardless of treatment, and the subject is disease free by the time the second period starts, this situation is also a period effect. In many crossover designs, the timing and spacing of periods is relatively loose. In clinical trials, the gap between periods may vary and may depend on when the patient can come in. Large numbers of periods are not suitable for animal feeding and clinical trials with humans. They may be used in psychological experiments with up to 128 periods.

Sequence effect is another issue in crossover design. Sequence refers to the order in which the treatments are applied. The possible sets of sequences that might be used in a design depend on the number of the treatments, the length of the sequences, and the aims of the experiment or trial. For instance, with t treatments there are $t!$ possible sequences. The measurement of sequence effect is the average response over the sequences. The simplest design is the two-treatment-two-period, or 2×2 , design. Different treatment sequences are used to eliminate sequence effects. The crossover design cannot accommodate a separate comparison group. Because each experimental unit receives all treatments, the covariates are balanced. The goal of the crossover design is to compare the effects of individual treatments, not the sequences themselves.

Variance Balance and Unbalance

In the feedstuffs example above, each treatment occurs one time in each experimental unit (or subject) and each of the six three-treatment sequences occurs two times, which confers the property of balance known as *variance balance*. In general, a crossover design is balanced for carryover effect if all possible sequences are used an equal number of times in the experiment, and each treatment occurs equal times in each period and occurs once with each experimental unit. However, this is not always possible; deaths and dropouts may occur in a trial, which can lead to unequal numbers in sequences.

In the example above and Table 1, $A \rightarrow B$ occurs twice, once each in Sequences 1 and 3; and $A \rightarrow C$ occurs once each in Sequences 4 and 5. Similarly, $B \rightarrow A$, $B \rightarrow C$, $C \rightarrow A$, and $C \rightarrow B$ each occur twice. For Experimental Units 1 and 2, $A \rightarrow B$ brings the first-order carryover effect in this experiment and changes

the response in the first period following the application of the treatment; similarly, the second-order carryover effect changes the response in the second period following the application of the treatment. A 21-day rest period is used to wash out the effect of treatment before the next treatment is applied. With the absence of carryover effects, the response measurements reflect only the current treatment effect.

In variance balance crossover design, all treatment contrasts are equally precise; for instance, in the example above, we have

$$\text{var}(\tau_A - \tau_B) = \text{var}(\tau_B - \tau_C) = \text{var}(\tau_A - \tau_C),$$

where var = variance and τ = a treatment group mean.

The contrasts of the carryover effects are also equally precise. The treatment and carryover effects are negatively correlated in crossover designs with variance balance.

Balanced crossover can avoid confounding the period effect with the treatment effects. For example, one group of experimental units received the $A \rightarrow C$, and another group of units received the sequence $C \rightarrow A$. These two treatments are applied in each period, and comparisons of Treatments A and C are independent of comparisons of periods (e.g., Period 1 and Period 2).

The *variance-balanced designs* developed independently by H. D. Patterson and H. L. Lucas, M. H. Quenouille, and I. I. Berenblut contain a large number of periods. These researchers showed that treatment and carryover effects are orthogonal. *Balaam designs* are also balanced, using t treatments, t^2 sequences, and only two periods with all treatment combinations, and they are more efficient than the two-period designs of Patterson and Lucas. Adding an extra period or having a baseline observation of the same response variable on each subject can improve the Balaam design. Generally, adding an extra period is better than having baselines. However, the cost is an important factor to be considered by the researcher.

Variance-unbalanced designs lack the property that all contrasts among the treatment effect and all contrasts among the carryover effects are of equal precision. For some purposes, the designer would like to have approximate variance balance, which can be fulfilled by the cyclic designs of A. W. Davis and W. B. Hall and the partially balanced incomplete block designs that exist in many of more than 60 designs included in the 1962 paper by Patterson and Lucas. One advantage of the Davis–Hall design is that it can be used for any number of treatments and periods. The efficiencies of Patterson and Lucas and Davis–Hall are comparable, and the designs of Davis and Hall tend to require fewer subjects. *Tied-double-changeover designs* are another type of variance-unbalanced crossover design proposed

by W. T. Federer and G. F. Atkinson. The goal of this type is to create a situation in which the variances of differences among treatments are nearly equal to the variances of differences among carryover effects. If Federer and Atkinson's design has t treatments, p periods, and c subjects, and we define two positive integers q and s , then $q = (p-1)/t$ and $s = c/t$. Some combinations of s and q make the design variance balanced.

Analysis of Different Types of Data

Approaches for Normally Distributed Data

The dependent variables follow a normal distribution. In general, let the crossover design have t treatments and n treatment sequence groups, let r_i = subjects in the i th treatment sequence group, and let each group receive treatments in a different order for p treatment periods. Then y_{ijk} is the response value of the j th subject of the i th treatment sequence in the k th period and can be expressed as

$$y_{ijk} = \mu + \alpha_i + \beta_{ij} + \gamma_k + \tau_{d(i,k)} + \lambda_{c(i,k-1)} + \varepsilon_{ijk}$$

$$i = 1, 2, \dots, n; j = 1, 2, \dots, r_i; k = 1, 2, \dots, p; d, c = 1, 2, \dots, t$$

where μ is the grand mean, α_i is the effect of the i th treatment sequence group, β_{ij} is the random effect of the j th subject in the i th treatment sequence group with variance σ_b^2 , γ_k is the k th period effect, $\tau_{d(i,k)}$ is the direct effect of treatment in period k of sequence group i , and $\lambda_{c(i,k-1)}$ is the carryover effect of the treatment in period $k-1$ of sequence group i . Note that $\lambda_{c(i,0)} = 0$ because there is no carryover effect in the first period. And ε_{ijk} is the random error for the j th subject in the i th treatment sequence of period k with variance σ^2 . This model is called a mixed model because it contains a random component. In order to simplify, let us denote Treatments A, B, and C as Treatments 1, 2, and 3, respectively. The first observed values in the first and second sequences of the example can be simply written

$$\text{Sequence 1}(A \rightarrow B)y_{111} = \mu + \alpha_1 + \beta_{11} + \gamma_1 + \tau_1 + \varepsilon_{111}$$

$$y_{112} = \mu + \alpha_1 + \beta_{11} + \gamma_2 + \tau_2 + \lambda_1 + \varepsilon_{111}$$

$$y_{113} = \mu + \alpha_1 + \beta_{11} + \gamma_3 + \tau_3 + \lambda_2 + \varepsilon_{113}$$

$$\text{Sequence 2}(B \rightarrow C)y_{211} = \mu + \alpha_2 + \beta_{21} + \gamma_1 + \tau_2 + \varepsilon_{211}$$

$$y_{212} = \mu + \alpha_2 + \beta_{21} + \gamma_2 + \tau_3 + \lambda_2 + \varepsilon_{212}$$

$$y_{213} = \mu + \alpha_2 + \beta_{21} + \gamma_3 + \tau_1 + \lambda_3 + \varepsilon_{213}.$$

From above, it may be seen that there is no carryover effect in the first period, and because only first-order carryovers are considered here, the first-order carryover effects of Treatments A and B are λ_1 and λ_2 , respectively, in Sequence 1. Likewise, the first-order

carryover effects of Treatments B and C are λ_2 and λ_3 , respectively, in Sequence 2. Actually, crossover designs are specific repeated measures designs with observed values on each experimental unit that are repeated under different treatment conditions at different time points. The design provides a multivariate observation for each experimental unit.

The univariate analysis of variance can be used for the crossover designs if any of the assumptions of independence, compound symmetry, or the Huynh-Feldt condition are appropriate for the experimental errors. Where independence and compound symmetry are sufficient conditions to justify ordinary least squares, the Huynh-Feldt condition (Type H structure) is both a sufficient and necessary condition for use of ordinary least squares. There are two cases of Analysis of Variance for crossover design: The first is the analysis of variance without carryover effect if the crossover design is a balanced row-column design. The experimental units and periods are the rows and columns of the design, and the direct treatment effects are orthogonal to the columns. The analysis approach is the same as that of a latin square experiment. The second is the analysis of variance with carryover effect, which is treated as a repeated measures split-plot design with the subjects as whole plots and the repeated measures over the p periods as the subplots. The total sum of squares is calculated from between and within subjects' parts. The significance of the carryover effects must be determined before the inference is made on the comparison of the direct effects of treatments.

For normal data without missing values, a least squares analysis to obtain treatment, period, and subject effect is efficient. Whenever there are missing data, within-subject treatment comparisons are not available for every subject. Therefore, additional between-subject information must be used.

In crossover design, the dependent variable may not be normally distributed, such as an ordinal or a categorical variable. The crossover analysis becomes much more difficult if a period effect exists. Two basic approaches can be considered in this case.

Approaches of Nonnormal Data

If the dependent variables are continuous but not normal, the Wilcoxon's rank sum test can be applied to compare the treatment effects and period effects. The crossover should not be used if there is a carryover effect, which cannot be separated from treatment effect or period effects. For this case, bootstrapping, permutation, or randomization tests provide alternatives to normal theory analyses. Gail Tudor and Gary G. Koch described the nonparametric method and its limitations

for statistical models with baseline measurements and carryover effects. Actually, this method is an extension of the Mann-Whitney, Wilcoxon's, or Quade's statistics. Other analytical methods are available if there is no carryover effect. For most designs, nonparametric analysis is much more limited than a parametric analysis.

Approaches for Ordinal and Binary Data

New statistical techniques have been developed to deal with longitudinal data of this type over recent decades. These new techniques can also be applied in the analysis of crossover design. A marginal approach using a weighted least square method is proposed by J. R. Landis and others. A generalized estimating equation approach was developed by Kung-Yee Liang and colleagues in 1986. For the binary data, subject effect models and marginal effect models can be applied. Bootstrap and permutation tests are also useful for this type of data. Variance and covariance structures need not necessarily be considered. The different estimates of the treatment effect may be obtained on the basis of different assumptions of the models. Although researchers have developed different approaches for different scenarios, each approach has its own problems or limitations. For example, marginal models can be used to deal with missing data, such as dropout values, but the designs lose efficiency, and their estimates are calculated with less precision. The conditional approach loses information about patient behavior and it is restricted to the logit link function. M. G. Kenward and B. Jones in 1994 gave a more comprehensive discussion of different approaches. Usually, large sample sizes are needed when the data are ordinal or dichotomous, which is a limitation of crossover designs.

Many researchers have tried to find an "optimal" method. J. Kiefer in the 1970s proposed the concept of *universal optimality* and named D-, A-, and E-optimality. The design is universally optimal and satisfies other optimal conditions, but it is extremely complicated to find a universally optimal crossover design for any given scenario.

CROSS-SECTIONAL DESIGN

The methods used to study development are as varied as the theoretical viewpoints on the process itself. In fact, often (but surely not always) the researcher's theoretical viewpoint determines the method used, and the method used usually reflects the question of interest. Age correlates with all developmental changes but poorly explains them. Nonetheless, it is often a primary variable of concern in developmental studies. Hence, the two traditional research designs, longitudinal methods, which examine one group of people (such as people born in a given year), following and reexamining them at several points in time (such as in 2000, 2005, and 2010), and cross-sectional designs, which examine more than one group of people (of different ages) at one point in time. For example, a study of depression might examine adults of varying ages (say 40, 50, and 60 years old) in 2009.

Cross-sectional studies are relatively inexpensive and quick to conduct (researchers can test many people of different ages at the same time), and they are the best way to study age *differences* (not age *changes*). On the other hand, a cross-sectional study cannot provide a very rich picture of development; by definition, such a study examines one small group of individuals at only one point in time. Finally, it is difficult to compare groups with one another, because unlike a longitudinal design, participants do not act as their own controls. Cross-sectional studies are quick and relatively simple, but they do not provide much information about the ways individuals change over time.

As with longitudinal designs, cross-sectional designs result in another problem: the confounding of age with another variable—the cohort (usually thought of as year of birth). *Confounding* is the term used to describe a lack of clarity about whether one or another variable is responsible for observed results. In this case, we cannot tell whether the obtained results are due to age (reflecting changes in development) or some other variable.

Confounding refers to a situation in which the effects of two or more variables on some outcome cannot be separated. Cross-sectional studies confound the time of measurement (year of testing) and age. For example, suppose you are studying the effects of an

early intervention program on later social skills. If you use a new testing tool that is very sensitive to the effects of early experience, you might find considerable differences among differently aged groups, but you will not know whether the differences are attributable to the year of birth (when some cultural influence might have been active) or to age. These two variables are confounded.

What can be done about the problem of confounding age with other variables? K. Warner Schaie first identified cohort and time of testing as factors that can help explain developmental outcomes, and he also devised methodological tools to account for and help separate the effects of age, time of testing, and cohort. According to Schaie, age differences among groups represent maturational factors, differences caused by when a group was tested (time of testing) represent environmental effects, and cohort differences represent environmental or hereditary effects or an interaction between the two. For example, Paul B. Baltes and John R. Nesselroade found that differences in the performance of adolescents of the same age on a set of personality tests were related to the year in which the adolescents were born (cohort) as well as when these characteristics were measured (time of testing).

Sequential development designs help to overcome the shortcomings of both cross-sectional and longitudinal developmental designs, and Schaie proposed two alternative models for developmental research—the *longitudinal sequential design* and the *cross-sectional sequential design*—that avoid the confounding that results when age and other variables compete for attention. Cross-sectional sequential designs are similar to longitudinal sequential designs except that they do not repeat observations on the same people from the cohort; rather, different groups are examined from one testing time to the next. For example participants tested in 2000, 2005, and 2010 would all come from different sets of participants born in 1965. Both of these designs allow researchers to keep certain variables (such as time of testing or cohort) constant while they test the effects of others.

CROSS-VALIDATION

Cross-validation is a data-dependent method for estimating the prediction error of a fitted model or a trained algorithm. The basic idea is to divide the available data into two parts, called *training data* and *testing data*, respectively. The training data are used for fitting the model or training the algorithm, while the testing data are used for validating the performance of the fitted model or the trained algorithm on predication purpose.

A typical proportion of the training data might be roughly 1/2 or 1/3 when the data size is large enough. The division of the data into training part and testing part can be done naturally or randomly. In some applications, a large enough subgroup of the available data is collected independently of the other parts of the data by different people or institutes or through different procedures but for similar purposes. Naturally, that part of the data can be extracted and used for testing purpose only. If such a subgroup does not exist, one can randomly draw a predetermined proportion of data for training purposes and leave the rest for testing.

K-Fold Cross-Validation

In many applications, the amount of available data is not large enough for a simple cross-validation. Instead, *K-fold cross-validation* is commonly used to extract more information from the data. Unlike the simple training-and-testing division, the available data are randomly divided into K roughly equal parts. Each part is chosen in turn for testing purposes, and each time the remaining $(K - 1)$ parts are used for training purposes. The prediction errors from all the K validations are collected, and the sum is used for cross-validation purposes.

In order to formulate the K -fold cross-validation using common notations, suppose the available data set consists of N observations or data points. The i th observation includes predictor(s) x_i in scalar (or vector) form and response y_i , also known as *input* and *output*, respectively. Suppose a random partition of the data divides the original index set $\{1, 2, \dots, N\}$ into K subsets $I(1), I(2), \dots, I(K)$ with roughly equal sizes. For the k th subset, let $\hat{f}^{-k}(\cdot)$ be the fitted prediction function based on the rest of the data after removing the k th subset. Then the K -fold cross-validation targets the average prediction error defined as

$$CV = \frac{1}{N} \sum_{k=1}^K \sum_{i \in I(k)} L(y_i, \hat{f}^{-k}(x_i)).$$

In the aforementioned expression, CV is average prediction error, $L(\cdot, \cdot)$ is a predetermined function, known as the *loss function*, which measures the difference between the observed response y_i and the predicted value $\hat{f}^{-k}(x_i)$. Commonly used loss functions $L(y, \hat{f})$ include the squared loss function $(y - \hat{f})^2$; the absolute loss function $|y - \hat{f}|$; the 0–1 loss function, which is 0 if $y = \hat{f}$ and 1 otherwise; and the cross-entropy loss function $-2 \log \hat{P}(Y = y_i | x_i)$, when a predicted probability is available.

The result CV of K -fold cross-validation depends on the value of K used. Theoretically, K can be any integer between 2 and the data size N . Commonly used values of K include 5 and 10. Generally speaking, when K is small, CV tends to overestimate the prediction error because each training part is only a fraction of the full data set. As K gets closer to N , the expected bias tends to be smaller, while the variance of CV tends to be larger because the training sets become more and more similar to each other. In the meantime, the cross-validation procedure involves more computation because the target model needs to be fitted for K times. As a compromise, 5-fold or 10-fold cross-validation would be suggested.

When $K = N$ is used, the corresponding cross-validation is known as *leave-one-out cross-validation*. It minimizes the expected bias but can be highly variable. For linear models using squared loss function, one may use the *generalized cross-validation* to overcome the intensive computation problem. It provides an approximated CV defined as

$$GCV = \frac{1}{N} \sum_{i=1}^N \left[\frac{y_i - \hat{f}(x_i)}{1 - \text{trace}(S)/N} \right]^2.$$

Here, S is an $N \times N$ matrix setting the fitting equation $\hat{y} = Sy$, and $\text{trace}(S)$ is the sum of the diagonal elements of S .

Cross-Validation Applications

The idea of cross-validation can be traced back to the 1930s. It was further developed and refined in the 1960s. Nowadays, it is widely used, especially when the data are unstructured or fewer model assumptions could be made. The cross-validation procedure does not require distribution assumptions, which makes it flexible and robust.

Choosing Parameter

One of the most successful applications of cross-validation is to choose a smoothing/tuning parameter or penalty coefficient. For example, a researcher wants to find the best function f for prediction purposes but is reluctant to add many restrictions. To avoid the overfitting problem, the researcher tries to minimize a penalized residual sum of squares defined as follows:

$$\text{RSS}(f, \lambda) = \sum_{i=1}^N [y_i - f(x_i)]^2 + \lambda \int [f''(x)]^2 dx.$$

Then the researcher needs to determine which λ should be used because the solution changes along with it. For each candidate λ , the corresponding fitted f is defined as the solution minimizing $\text{RSS}(f, \lambda)$. Then the cross-validation can be applied to estimate the prediction error $\text{CV}(\lambda)$. The optimal λ according to cross-validation is the one that minimizes $\text{CV}(\lambda)$.

Model Selection

Another popular application of cross-validation is to select the best model from a candidate set. When multiple models, or methods, or algorithms are applied to the same data set, a frequently asked question is which one is the best. Cross-validation provides a convenient criterion to evaluate their performance. One can always divide the original data set into training part and testing part. Fit each model based on training data and estimate the prediction error of the fitted model based on the testing data. Then the model that attains the minimal prediction error is the winner.

Two major concerns need to be addressed for the procedure. One of them is that the estimated prediction error may depend on how the data are divided. The value of CV itself is random if it is calculated based on a random partition. To compare two random CVs, one may need to repeat the whole procedure for many

times and compare the CV values on average. Another concern is that the selected model may succeed for one data set but fail for another because cross-validation is a data-driven method. In practice, people tend to test the selected model again when additional data are available via other sources before they accept it as the best one.

Cross-validation may also be needed during fitting a model as part of the model selection procedure. In the previous example, cross-validation is used for choosing the most appropriate smoothing parameter λ . In this case, the data may be divided into three parts: training data, validation data, and testing data. One may use the validation part to choose the best λ for fitting the model and use the testing part for model selection.

A Wrong Way to Do Cross-Validation

When the prediction problem under consideration involves many predictors, variable selection or screening is commonly used. It is often critical to distinguish whether the variable selection is only based on training data or not. If the variable selection is performed using the whole data set, then the prediction error estimated by cross-validation after variable selection could be misleading.

For example, a “large p , small n ” simulation study was described by Hastie, Tibshirani, and Friedman (2009). To predict a binary response Y with sample size $n = 50$, one generates $p = 5,000$ predictors independently from the standard normal distribution. Since these predictors are independent of Y , the error rate of any prediction function is expected to be 50% if Y has two equal-sized classes. However, if a variable selection procedure is performed to choose the top 100 predictors using all the 50 samples, and a fivefold cross-validation procedure is used to estimate the predictor error based on the 100 chosen predictors, then the estimated prediction error rate could be as low as 2%. To avoid a potential underestimate of the prediction error, variable selection should be restricted to training data only.

CULTURAL COMPETENCE

The term *cultural competence* describes the degree to which an individual shares with others an understanding of his or her own culture. Cultural competence in this sense rests on a cognitive definition of culture: that which one needs to know to function adequately in a given community. Methodological developments since the 1980s have led to the precise operationalization of the concept of cultural competence, based on cultural consensus analysis. This entry first explains the process of cultural consensus analysis and then discusses developments since the introduction of the model to further the understanding of cultural competence and cultural consensus.

Cultural Consensus Analysis

Cultural consensus analysis is a fully axiomatic, deductive model for estimating cultural competence. Cultural consensus analysis can be viewed as a step in the broader approach referred to as *cultural domain analysis*. Research guided by cognitive culture theory emphasizes an *emic* approach in which key terms are operationalized in reference to meaningful distinctions made by members of a study community, not in reference to terms imposed on the community by the researcher. A simple example of this is the term *family*. In many communities (e.g., the African American community in the United States), a family extends across a much wider set of kinship relationships than is often the case in the European American middle class (the reference community of many researchers). In an *emic* approach, meaningful distinctions are elicited from community members, and these distinctions are used to operationalize key explanatory terms. Cultural domain analysis is an integrated set of data elicitation and analytic techniques to carry out research using an *emic* approach.

Cultural consensus analysis can be used to verify that community members share an understanding of a cultural domain (an organized sphere of discussion, such as *the family*). In the original formulation of the cultural consensus model, it was assumed that (1) there is a single, shared cultural model organizing the cultural domain; (2) individuals share, to a variable degree, an understanding of that model; and (3) data regarding the model have been independently collected from respondents.

The data for input to cultural consensus analysis can take a variety of forms including true–false questions, multiple-choice questions, ranking tasks, and rating tasks. For example, in a study of the family as a cultural

domain, an investigator would elicit a set of terms that describe the prototypical family in a particular community (e.g., hardworking, mutually supportive, caring, well-organized) from a diverse set of respondents. The set of terms would then be reduced to those most frequently used (in typical analyses from 25 to 50 terms would be retained). Another set of respondents would then be asked to rank those terms from most to least important in “having a family.”

At this point, cultural consensus analysis would be used to examine the patterned similarity among the respondents in answering these questions: How similar are the profiles of responses to the questions for each pair of respondents? If these profiles are similar enough, then it is reasonable to infer that each respondent is drawing on a common underlying pool of cultural knowledge in his or her responses? Although it is not a factor analysis per se, cultural consensus analysis uses factor analytic methods to estimate overall profile similarity among the respondents. Using minimum residual factor analysis, the first two or three factors are extracted from a respondent-by-respondent correlation matrix (matching coefficients for nominal data, Pearson’s *r* for rating or ranking tasks). If the first factor explains a large amount of variance relative to the second, this indicates a large amount of agreement among respondents, and it is reasonable to infer they are using a common underlying cultural model in their rankings. A rule of thumb of 3.0 for the ratio of the first-to-second eigenvalue has been commonly used as a minimum criterion. The more that this ratio exceeds 3.0, the stronger the sharing of the cultural model.

The loading of a respondent on the first factor is his or her cultural competence. In terms of conventional factor analysis, this would be interpreted as the correlation between that individual’s responses to the questions and the aggregated responses. This coefficient can be interpreted more specifically in cultural consensus analysis. With nominal data, the cultural competence coefficient is the proportion of questions for which the respondent answered with the “culturally correct” (i.e., most agreed on) response. For ratings or rankings, the cultural competence coefficient is the proportion of questions that the respondent ranked in the same order as the culturally correct responses. The correlation between any pair of respondents is the product of their respective cultural competence.

Cultural competence also figures prominently in estimating the “cultural answer key” or an estimate of the “culturally best” responses to the question. For nominal data, this is a Bayesian estimate of the best response, and for ratings and rankings, standard factor

scores are used. In either case, the culturally correct responses are estimated giving greater weight to those respondents who agree more strongly with more other respondents.

Cultural consensus analysis has been put to a variety of uses, including the study of the sharing, variation, and distribution of knowledge in a variety of cultural domains such as health and disease, social relationships, ethnobotany, ethnoecology, and others. In these cases, cultural competence coefficients can be used as a dependent variable to examine how the sharing of culture varies within and between groups.

Recent Developments

A number of developments have enhanced the study of cultural competence and cultural consensus since the introduction of the model. In particular, greater attention has been devoted to the analysis of intracultural variation, both in terms of the distribution of cultural competence (as described earlier) and in terms of the identification of patterns of agreement that go beyond the overall cultural consensus. The latter is referred to as *residual agreement*. It has been shown that even in cultural models where there is high consensus, subgroups within the sample can emphasize certain aspects of the model over others.

Also, cultural consensus analysis has been used as a foundation for the development of measures of cultural consonance or the degree to which individuals approximate the cultural consensus in their own individual beliefs and behaviors. Low cultural consonance is a stressful experience found to be associated with a variety of poor health outcomes. The operationalization of cultural competence using the cultural consensus model has provided new insights into many basic questions in anthropology and other social sciences.

CUMULATIVE FREQUENCY DISTRIBUTION

Cumulative frequency distributions report the frequency, proportion, or percentage of cases at a particular score or less. Thus, the cumulative frequency of a score is calculated as the frequency of occurrence of that score plus the sum of the frequencies of all scores with a lower value. Cumulative frequency distributions are usually displayed with the aid of tables and graphs and may be put together for both ungrouped and grouped scores.

Cumulative Frequency Tables for Distributions With Ungrouped Scores

A cumulative frequency table for distributions with ungrouped scores typically includes the scores a variable takes in a particular sample, their frequencies, and the cumulative frequency. In addition, the table may include the cumulative relative frequency or proportion, and the cumulative percentage frequency. Table 1 illustrates the frequency, cumulative frequency, cumulative relative frequency, and cumulative percentage frequency for a set of data showing the number of credits a sample of students at a college have registered for in the autumn quarter.

The cumulative frequency is obtained by adding the frequency of each observation to the sum of the frequencies of all previous observations (which is, actually, the cumulative frequency on the previous row). For example, the cumulative frequency for the first row in Table 1 is 1 because there are no previous observations. The cumulative frequency for the second row is $1 + 0 = 1$. The cumulative frequency for the third row is $1 + 2 = 3$. The cumulative frequency for the fourth row is $3 + 1 = 4$, and so on. This means that four students have registered for 13 credits or fewer in the autumn quarter. The cumulative frequency for the last observation must equal the number of observations included in the sample.

Cumulative relative frequencies or cumulative proportions are obtained by dividing each cumulative frequency by the number of observations. Cumulative proportions show the proportion of observations that fulfill a particular criterion or less. For example, the proportion of students who have registered for 14

Table 1 Cumulative Frequency Distribution of the Number of Credits Students Have Registered for in the Autumn Quarter

<i>Number of credits y</i>	<i>Frequency f</i>	<i>Cumulative frequency cum(f)</i>	<i>Cumulative relative frequency cumr(f) = cum(f)/n</i>	<i>Cumulative percentage frequency cump(f) = 100*cumr(f)</i>
10	1	1	0.10	10.00
11	0	1	0.10	10.00
12	2	3	0.30	30.00
13	1	4	0.40	40.00
14	2	6	0.60	60.00
15	4	10	1.00	100.00%
<i>n = 10</i>				

Table 2 Grouped Cumulative Frequency Distribution of Workers' Salaries

<i>Workers' salaries y</i>	<i>Frequency f</i>	<i>Cumulative frequency cumr(f)</i>	<i>Cumulative relative frequency cumr(f) = cum(f)/n</i>	<i>Cumulative percentage frequency cump(f) = 100*cumr(f)</i>
\$15,000–\$19,999	4	4	0.27	26.67
\$20,000–\$24,999	6	10	0.67	66.67
\$25,000–\$29,999	3	13	0.87	86.67
\$30,000–\$34,999	0	13	0.87	86.67
\$35,000–\$39,999	2	15	1.00	100.00%
<i>n = 15</i>				

credits or fewer in the autumn quarter is 0.60. The cumulative proportion for the last observation (last row) is always 1.

Cumulative percentages are obtained by multiplying the cumulative proportions by 100. Cumulative percentages show the percentage of observations that fulfill a certain criterion or less. For example, 40% of students have registered for 13 credits or fewer in the autumn quarter. The cumulative percentage of the last observation (the last row) is always 100.

Grouped Cumulative Frequency Distributions

For distributions with grouped scores, the cumulative frequency corresponding to each class equals the frequency of occurrence of scores in that particular class plus the sum of the frequencies of scores in all lower classes (which is, again, the cumulative frequency on the previous row). Grouped cumulative frequency distributions are calculated for continuous variables or for

discrete variables that take too many values for the list of all possible values to be useful. The cumulative distribution table for this case is very similar to Table 1, and the entries in the table are computed in a similar way. The only difference is that instead of individual scores, the first column contains classes. Table 2 is an example of a cumulative frequency table for a sample of workers' salaries at a factory.

The cumulative frequency of a particular class is calculated as the frequency of the scores in that class plus the sum of the frequencies of scores in all lower classes. Cumulative frequencies in Table 2 show the number of workers who earn a certain amount or money or less. For example, the reader learns that 10 workers earn \$24,999 or less.

Cumulative relative frequencies or proportions show the proportion of workers earning a certain amount of money or less and are calculated by dividing the cumulative frequency by the number of observations. For example, the proportion of workers earning \$29,999 or less is 0.87.

Finally, cumulative percentages show the percentage of workers earning a certain amount of money or less, and these percentages are obtained by multiplying the cumulative relative frequency by 100. For example, 86.67% of workers earn \$34,999 or less. The last row shows that 15 workers, representing all the workers included in the analyzed sample (100%), earn \$39,999 or less. The cumulative proportion of the workers in this last class is, logically, 1.

Graphing Cumulative Distributions of Discrete Variables

Cumulative frequencies, cumulative proportions, and cumulative percentages of a discrete variable can all be represented graphically. An upper right quadrant of a two-dimensional space is typically used to display a cumulative distribution. The quadrant is bounded by an x -axis and a y -axis. The x -axis is positioned horizontally and usually corresponds to the scores that the variable can take. The y -axis indicates the cumulative frequency, proportion, or percentage. Cumulative distributions may be graphed using histograms or, more commonly, polygons.

To exemplify, the number of credits from Table 1 is plotted in Figure 1. The number of credits the students have registered for is represented on the x -axis. The cumulative frequency is represented on the y -axis. Using each score and its corresponding cumulative frequency, a number of points are marked inside the quadrant. They are subsequently joined to form a polygon that represents the cumulative frequency distribution graph.

Graphing Grouped Cumulative Distributions

Grouped cumulative frequency distributions may also be graphed via both histograms and polygons. Again, it is

Figure 1 Cumulative Frequency Distribution of the Number of Credits Students Have Registered for in the Autumn Quarter

more common to use cumulative frequency (or proportion or percentage) polygons. To draw the polygon for a grouped distribution, the points represented by the mid-point of each class interval and their corresponding cumulative frequency are connected.

To exemplify, the cumulative frequency distribution described in Table 2 is graphically illustrated in Figure 2.

Shape of Cumulative Distributions

Cumulative polygons are often referred to as ogives. They climb steeply in regions where classes include many observations, such as the middle of a bell-shaped distribution, and climb slowly in regions where classes contain fewer observations. Consequently, frequency distributions with bell-shaped histograms generate S-shaped cumulative frequency curves. If the distribution is bell shaped, the cumulative proportion equals 0.50 at the average of the x value, which is situated close to the midpoint of the horizontal range. For positive skews, the cumulative proportion reaches 0.50 before the x average. On the contrary, for negative

Figure 2 Grouped Cumulative Frequency Distribution of Workers' Salaries

Figure 3 Cumulative Percentage Frequency Distribution of the Number of Credits Students Have Registered for in the Autumn Quarter

skews, the cumulative proportion reaches 0.50 further away to the right, after the x average.

Many statistical techniques work best when variables have bell-shaped distributions. It is, however, essential to examine the actual form of the data distributions before one uses these techniques. Graphs provide the simplest way to do so, and cumulative polygons often offer sufficient information.

Using Cumulative Distributions in Practice

Cumulative frequency (or proportion or percentage) distributions have proved useful in a multitude of research spheres. Typically, cumulative percentage curves allow us to answer questions such as, What is the middle score in the distribution? What is the dividing point for the top 30% of the group? Consequently, cumulative percentage curves are used by instructors in schools, universities, and other educational centers to determine the proportion of students who scored less than a specified limit. Doctors' offices may use cumulative weight and height distributions to investigate the percentage of children of a certain age whose weight and height are lower than a certain standard. All this is usually done by using cumulative frequency distributions to identify percentiles and percentile ranks. Consequently, the cumulative frequency curve is also known as the *percentile curve*.

Finding Percentiles and Percentile Ranks From Cumulative Distributions

A percentile is the score at or below which a specified percentage of scores in a distribution falls. For example, if the 40th percentile of an examination is 120, it means that 40% of the scores on the examination are equal to or less than 120. The percentile rank of a score indicates the percentage of scores in the distribution that are equal to or less than that score. Referring to the above example, if the percentile rank of a score of 120 is 40, it means that 40% of the scores are equal to or less than 120.

Percentiles and percentile ranks may be determined with certain formulas. Nevertheless, as already mentioned, the cumulative distribution polygon is often used to determine percentiles and percentile ranks graphically. To exemplify, Figure 3 shows the cumulative percentage frequency distribution for the data in Table 1, with the cumulative percentage/percentile scale represented on the y -axis and the number of credits on the x -axis.

To determine the percentile rank corresponding to 12 credits, a perpendicular is erected from the x -axis at point 12 until it meets the cumulative polygon. A horizontal line is then drawn from this point until it meets

the y -axis, which is at point 30 on the percentile scale. This means that 30% of the students have registered for 12 credits or fewer for the autumn quarter. The cumulative percentage frequency data shown in Table 1 confirm this result. The method may be employed the other way around as well. The percentile rank may be used to determine the corresponding percentile. Drawing a horizontal line from the point 60 on the percentile scale to the cumulative polygon and then a perpendicular on the x -axis from the point of intersection, the point (0, 14) is met. In other words, the 60th percentile corresponds to 14 credits, showing that 60% of the students have registered for 14 credits or fewer. The midpoint in a distribution is often known as the 50th percentile, the median, or the second quartile. It represents the point below which we find 50% of the scores and above which the other 50% of the scores are located. The 10th percentile is called the first decile, and each multiple of 10 is referred to as a decile. The 25th percentile is the first quartile, and the 75th percentile is the third quartile. This is a very simple method to determine the percentile rank corresponding to a particular score. However, the method may not be always accurate, especially when a very fine grid is not available.

CUT SCORES

It is often necessary to take the scores from a test and create two or more groups of examinees. For example, in licensure testing, a threshold score on a test is

necessary (although there may be additional requirements) to be allowed to practice a particular profession. For a state educational test required to meet federal accountability laws, some scores might lead a student to be classified as below basic, basic, proficient, or advanced in a particular discipline such as mathematics. Cut scores are the numeric value representing the test score that separates one category of examinees from another. The process by which cut scores are set, also referred to as *standard setting*, is done when stakeholders and policy makers, usually facilitated by measurement experts, try to best create discrete groups from a continuous construct. Cut scores are necessary when the purpose of any test, such as an academic or occupational test, is to provide stakeholders with some sort of pass/fail metric on which to make a decision about the test taker. This entry presents the fundamentals of understanding cut scores and the process by which they are set as well as a number of examples of common cut-score-setting methods.

Nomenclature and Definition of Task

A plethora of nomenclature surrounds cut scores. For different testing scenarios, cut scores may be referred to in a number of ways, such as achievement levels, classification boundaries, criterion levels, cutoff scores, mastery levels, passing scores, or performance standards. Typically, the first steps of a cut-score-setting study establish consistent wording around what exactly the goal of the cut-score-setting study will be and how the cut scores will be referred to for general public understanding.

Another priority is establishing which type of cut score—absolute or relative—is to be set. Absolute cut scores are criterion referenced and depend on the test taker's knowledge and skill level of the tested construct. On a test using an absolute cut score, all examinees can pass or all examinees can fail. All cut-score-setting methods discussed in this entry are for setting absolute cut scores.

Relative cut scores are normative and depend on where the test taker falls within the distribution of test takers. Relative cut scores are sometimes used for hiring or promotion. For example, the top 20% of performers in an entry-level position may be promoted based on their performance on a job test.

Definition of task is similar to nomenclature in that it involves defining exactly what a cut-score study is and is not. Setting cut scores is the process of creating a decision rule on the basis of test scores; however, the knowledge or skills being tested fall along a continuum and thus do not fall perfectly into the defined groups.

This leads to problems such as people with adjacent scores falling on either side of a cut score, while they are not substantially different in true score and have standard errors that exceed one raw score point. Establishing cut scores forces a break in the continuous distribution, where the side of the cut score that a test taker falls on could have drastic impacts on that person's life even though the test cannot reliably distinguish between the scores directly adjacent to the cut score. Everyone involved in the cut-score-setting study must have an understanding of the nomenclature and definition of task and keep it in mind when making decisions during the process.

Necessity of Judgment and Errors of Classification

At their heart, cut scores are a judgment as to how good is good enough. As judgments, cut scores are not found, they are constructed. For the purposes of this entry, three broad categories of cut-score studies are defined: (1) judgments about people, (2) judgments about examinee responses, and (3) judgments about test items. Making judgments about people involves making decisions and judgments about the test takers themselves. Making judgments about examinee responses involves making decisions about the products produced by examinees. Making judgments about test items involves making decisions about the items themselves and what they represent in terms of the construct. Methods where experts make judgments about people or examinee responses can work well because doing so involves a concrete task that uses empirical data. Results are easy to explain but can be expensive and require that data are collected before a cut score can be set. Using judgments of test items is advantageous because that is a more convenient method and less costly, lots of judges can be used, it is widely applied, and a plethora of research is available on this class of methods. However, item judgment approaches are based on opinions about a hypothetical group and is frequently attacked as flawed. While having data is not absolutely necessary for item-judgment methods, which depend on estimates about how a hypothetical group of borderline people will respond to the items, it is still useful to have some data-based checks. Even though item-judgment methods are heavily criticized, they are still widely used.

Because cut scores are constructed as products of judgment, errors of classification will happen regardless of where a cut score is set. Some people who pass should fail, and some people who fail should pass. This is due to error and the fact that the lower end of the distribution of those who should pass overlaps with the

Figure 1 Determining a Cut Score for Overlapping Distributions

Figure 2 Determining a Cut Score by Where Distributions Cross

higher end of the distribution of those who should fail, as shown in Figure 1. Raising or lowering a cut score to reduce one type of error will inevitably increase the other. Given that the left normal distribution includes those who should fail and the right distribution includes those who should pass, where should a vertical line be drawn as a cut score?

Sometimes the cut score will be drawn where the distributions cross, as shown in Figure 2.

In the scenario proposed in Figure 2, the proportions of people who passed but should have failed and people who failed but should have passed are equal, assuming that true fail and true pass have the same standard deviation. Depending on the consequences of false passes and false fails, it might make sense for those rates to be asymmetrical. For example, the consequences of a false pass may be very high if an incompetent surgeon were allowed to practice. For such an examination, the cut score could be increased, even though this would increase the proportion of those who fail who should have passed, as shown in Figure 3.

Similarly, if it is vital that everyone who should pass does so, the cut score could be lowered, but then more people who should fail would pass, as shown in Figure 4.

Evaluating the relative harm caused by errors of classification is essential, since errors of classification bring consequences. Based on the pass-or-fail decision that is made, there may be more consequences for landing on one side of a cut score than on the other—an example being the potential harm caused when people who should have failed in large numbers instead passed, such as a high number of people passing a

Figure 3 Increasing a Cut Score to Decrease False Passes

Figure 4 Decreasing a Cut Score to Increase True Passes

medical certification exam when they are not qualified to be a medical practitioner. Another consideration would be how severely failing *versus* passing could affect someone's life; for example, if a person fails when they should have passed, the degree to which that will alter the trajectory of their life must be considered. Most likely a little bit of each error will be sufficient; however, the group setting the cut scores, especially policy makers and stakeholders, must evaluate the values and how acceptable error is influenced by them.

Methods to Set Cut Scores

With any measurement topic, one must be mindful of limitations. There is no universally accepted way to set cut scores. No matter how it is done, someone will say it was done incorrectly. Often, cut scores are labeled as arbitrary but the fact that they are based on judgments does not necessarily mean they are illogical.

Many methods for setting cut scores require selecting judges to set the cut scores. When selecting judges, the cut-score-setting team aims to choose a representative and diverse group of judges who are knowledgeable on the subject being tested and the population of test takers—and who are acceptable to stakeholders. The team then educates the judges about cut scores and the fundamentals of understanding cut scores, making sure the judges understand the test's purpose, the

purpose of cut scores, the judge's role in the cut-score-setting process, the consequences of categorizing test takers into different levels, the nature of the test takers, test content, and the errors of classification.

Then, the team trains the judges in the selected method. They give the judges an overview of the process, teach them what to do and how and why it should be done that way. The cut-score-setting study team also observes the judges as they practice, corrects any errors, and answers all their questions. Once all of the judges are prepared and documentation of their understanding is made, the cut-score-setting study can begin. Using the selected method, the study team and judges complete an iteration of a cut-score-setting study. The study team documents the process and outcomes along the way. Operational cut scores may need to be defended in the future, so the study team should prepare for that defense meticulously. It can be helpful for the team to document everything in a way that could be published and made widely available as technical documentation. After recommended cut scores based on the results from the study have been created and how and why these recommendations were made has been documented, the next step is the creation of the operational cut scores, which will be implemented on the test and must be set by legally authorized personnel. The recommended cut scores from the study may not become the operational cut scores without some adaptation. Often policy makers will consider relative harm caused by errors of classification, credibility, acceptance, policy issues, test purpose, and alignment with other cut scores when adjusting the recommended cut scores to create operational ones. Finally, the cut-score-setting team ensures that the documentation aligns with standards for cut scores, documenting such standards as how judges were selected and how scores are interpreted based on cut scores.

When selecting a method to use, the study team often considers person-judgment-based methods *versus* product-judgment-based methods *versus* item-judgment-based methods. Possible choices include two common person-judgment-based methods: the borderline-group method and the contrasting-groups method. There is one common product-judgment-based method: body of work. There are also three common item-judgment-based methods: the Nedelsky method, the Angoff method, and the bookmark method.

Person-Judgment-Based Methods

Borderline-Group Method

The borderline-group method involves judges identifying people whose scores are borderline, based on the established definition of borderline. This refers to

people the judges believe are not quite at the level of passing but not really part of the group that should fail either. This method requires the judges to make a decision about the person based on observed factors pertaining to the construct of interest. Once the borderline group of people is identified, their test scores are collected. Then the median score of those people is calculated to represent the cut score. This method requires data to be collected prior to cut score setting.

Contrasting-Groups Method

The goal of the contrasting-groups method is to find the cut score that causes the fewest errors in classification. This method includes the following steps:

- (1) Select a representative sample of test takers.
- (2) Obtain judgments of each examinee as someone who should pass or someone who should fail the test, then obtain scores for that sample.
- (3) Compute the percentage of people in the should-pass group at each score level.
- (4) Select a cut score based on a point at which the probability of being in the should-pass group is 0.5 or 50%.

If needed, adjustments can be made to minimize harmful errors of classification, based on accepted probability of passing when one should fail or failing when one should pass. This method has a number of pitfalls, including its heavy reliance on human judgment, its requirement for a lot of knowledge about the test takers, the length of time it takes, and its need for data that have previously been collected.

Product-Judgment-Based Methods

Body-of-Work Method

The body-of-work method is used when the work of test takers, such as essays, can be evaluated. This method is difficult to apply with multiple-choice items. Typically, this method involves the judges reviewing the body of work, also called *response booklets*, on which they are to evaluate the test taker without knowing what score the test taker received. After reviewing these response booklets, the judges place them into categories such as *basic*, *proficient*, and *advanced*. Once all response booklets have been evaluated by each judge and placed into a specific group, the test-taker scores associated with those booklets are revealed. The distribution of scores assigned to each group influences where the cut score is set by indicating the point where two adjacent performance levels are best distinguished from one another.

Item-Judgment-Based Methods

Nedelsky Method

The Nedelsky method takes the definition of a borderline test taker and judges how that test taker will respond to multiple-choice questions. Justification of the Nedelsky method comes from the assumption that when unsure of an answer, test takers eliminate answer options they know are incorrect and then select at random from the remaining answers. The Nedelsky method has the judges imagine which answer options a person from the borderline group will omit for a given item; expected total score can then be calculated from the remaining possibilities across all items. The cut score placement can then be based on the expected score the judges give a test taker who fits the definition of borderline.

Angoff and Modified Angoff Methods

The Angoff method relies heavily on judgment of borderline test takers. The original method asks judges to determine whether or not a borderline test taker would answer each item correctly. The number of items that judges believe a borderline person would answer correctly then becomes the cut score. Adjustments to this procedure result in a modified Angoff method, wherein judges gauge the probability that each borderline test taker will answer each item correctly; the probabilities are then summed for a cut score. Other modifications include establishing a number of rounds for making judgments, particularly sequential *versus* simultaneous judgments; gathering feedback; and promoting discussions. The Angoff method is similar to the Nedelsky method, except it can also make judgments about constructed-response items through mean estimation.

Bookmark Method

The bookmark method is structured to evaluate increasing knowledge and skills directly against academic standards. Essentially, the items are being ordered from easiest to hardest, and a cut score is drawn at the point where the increasing knowledge and skills are deemed sufficient. In this method, technology-enhanced, constructed-response, and multiple-choice items are ordered together, often splitting the difficulty into parts

based on point values (i.e., how difficult it is to earn one point or two points on a given item). The goal of the bookmark method is to find the last item that a borderline test taker would answer with a set probability, often 0.66. This method is appealing because of its logistic simplicity, cognitive ease for judges, and ability to handle an array of item types simultaneously.

D

DATA AND SAFETY MONITORING

Data and safety monitoring (DSM) refers to a set of oversight procedures in research studies involving human subjects. Depending on the nature and complexity of the study, DSM is carried out not just during the study but often before and after it as well.

Data monitoring refers to the oversight of the research data to help ensure their validity and integrity and to determine whether and to what extent they adequately serve the goals of the study and subject safety. For instance, in a clinical trial designed to test whether a given drug is more effective than placebo in reducing heart attack rates, the plan for data collection must be scrutinized for its appropriateness to achieve study goals before the study even begins. During the study, the accumulated data must be evaluated periodically to determine whether and how the study procedures need to be modified to better achieve study goals and subject safety. If at any point the data indicate with sufficient confidence that the drug is effective, ineffective, or harmful, the relevant arms of the study may have to be stopped prematurely while the other arms are allowed to proceed. Especially in such cases, data monitoring may have to proceed in ongoing arms of the study even as the results from the finished arms of the study are disseminated.

Safety monitoring refers to the oversight of the safety of human subjects participating in the research. Before the study begins, the entire protocol must be vetted for subject safety measures. During the study, incidents that potentially represent adverse or unanticipated outcomes must be examined in order to evaluate whether they are study-related and whether and how the study needs to be modified. For instance,

in the aforementioned example, reported instances of fainting may or may not be caused or expected from a given study drug.

While the two types of monitoring can be conceptualized separately, it rarely makes sense to fully separate them in practice because they are intimately related. Therefore, the two types of monitoring are almost always implemented as a single, integrated package of monitoring procedures, even though the underlying responsibilities may be delegated differentially among different specialists in the DSM workflow.

This entry reviews the core principles, regulatory underpinnings, and historical background of DSM before detailing the basic elements of DSM design and operation.

Core Principles of DSM

The actual DSM practices can vary across studies, institutions, and regulatory jurisdictions. Nonetheless, certain basic principles guide DSM everywhere. Prominent among these are

1. The level and type of monitoring needed depend on multiple factors, including especially the complexity of the study and the type and level of risk to subjects.
2. The ultimate goals of DSM are distinct from, and independent of, the study goals. In case of a conflict, the former always trump the latter. Therefore, DSM should be carried out objectively, and regardless of how it may affect the study outcomes.
3. DSM should be flexible and dynamic enough to continually adapt and respond to study events and developments.

4. All the stakeholders in the study—including the principal investigator (PI), the rest of the study team, the institutional review board (IRB), study sponsors, and external monitoring entities, if any—should work cooperatively and exercise their own appropriate level of monitoring, however, formally or informally.

In sum, DSM is simply common-sense research vigilance operationalized.

Regulatory Underpinnings of DSM

In the developed world, the ultimate rules pertaining to DSM are codified in governmental regulations and therefore have the force of law. In the United States, the underlying procedural requirements are covered by the U.S. code of federal regulations Titles 21 and 45. U.S. regulations and guidelines pertaining to DSM apply to all studies approved in the United States, regardless of whether the sponsor or the study site is within or outside the United States or whether the study is also subject to regulatory oversight in another jurisdiction.

In the United States, all clinical studies that involve greater than minimal risk to participants are required to have in place some level of DSM commensurate with the risk. Strictly speaking, DSM is not required for nonclinical trials. Nonetheless, IRBs may, and often do, require some level of DSM for such studies commensurate with the risk. While research in animal subjects in the United States is covered by an entirely independent set of regulations, the underlying DSM principles and practices tend to be similar and are routinely referred to as DSM in research protocols, funding applications, and research publications.

Numerous other countries around the world have comparable DSM requirements for clinical research. Depending on the country, these requirements tend to be more or less consistent with the international guidelines for clinical research set forth by the World Health Organization (WHO). Compliance with the international standards is especially important these days because health-care research, development, and delivery as well as pharmaceutical manufacturing and marketing are increasingly globalized, as are many of the major health concerns.

Historical Background

The origins of DSM can be traced to the landmark 1964 Declaration of Helsinki that set forth broad ethical principles for biomedical research involving human subjects worldwide and the April 1979 Belmont Report by a U.S. government-appointed

commission on the topic. Many of the current practices and even the phraseology of DSM stem from a June 1979 recommendation of the Clinical Trials Committee of the U.S. National Institutes of Health (NIH) that applied the ethical principles specifically to clinical trials and called for every clinical trial to “have provision for data and safety monitoring.” Since then, other influential organizations around the world, including the WHO, European Medicines Agency (EMA), and the U.S. Food and Drug Administration (FDA), have issued comparable guidelines that apply to clinical research carried out under their aegis.

The overall rationale for DSM rests on the fact that the success of any clinical study requires that the investigators as well as the study subjects meet certain obligations. On the one hand, the investigators must protect the health and safety of study subjects; inform the subjects about the risks, rigors, and responsibilities that participation in the study entails; afford the subjects the opportunity to withdraw from the study if they so desire; and pursue the objectives of the study with diligence. On the other hand, the study subjects must comply with the study requirements as long as they participate in the study. The sponsors and the IRB must ensure that the potential risks to the study subjects are commensurate with the potential benefits to the society and to the subjects and are properly managed throughout the study. The purpose of DSM is to ensure that all these interests are properly balanced and safeguarded throughout the study.

Basic Elements of DSM Design and Operation

Designing DSM procedures is an integral part of developing the study protocol. DSM procedures must be custom-developed for each study because there is no standard set of DSM practices that is *a priori* suitable for all studies.

In determining the proper level of DSM for a given study, it is wise to err on the side of caution, especially where risks to the subjects are substantial. However, unnecessary DSM has its costs too because it can be wasteful and unnecessarily impede the study. Ultimately, it is the responsibility of the PI to balance these competing considerations, plan the DSM procedures appropriately for the given study in consultation with the IRB, and obtain the approval of the IRB for the protocol prior to starting the study. Once the study gets underway, the PI is ultimately responsible for carrying out the study procedures, including DSM, according to the approved protocol.

Data and Safety Monitoring Plan (DSMP)

DSMP refers to a written document that specifies all aspects of DSM in a given study. IRBs typically require a DSMP as a part of any protocol of a clinical trial. Similarly, most sponsors of clinical trials also require a DSMP as a part of the grant application for funding. For instance, NIH requires a DSMP that addresses specific topics as a part of the *Human Subjects* section of all proposals for grants or contracts to fund clinical trials. As to the specific format and the required content of the DSMP, the IRB and/or the given funding agency should be consulted.

IRB

In its capacity as the intramural regulator of record, the IRB has considerable powers of oversight and enforcement pertaining to DSM. Before the study can begin, the IRB reviews the study, requires appropriate modifications where necessary, and approves the study if all aspects of the study, including the DSM plans, are adequate. While the study is ongoing, the IRB typically has two types of DSM oversight functions. First, as a part of its periodic review of the study, it monitors compliance with the approved DSM procedures. Second, it reviews, on an *ad hoc* basis, the reports of study developments and reportable events submitted to it by the PI or other cognizant parties such as the sponsor. Based on its review, the IRB may accept the recommendations (if any) of the cognizant parties, suspend or terminate the study activities, or require modifications to one or more aspects of the study, including DSM procedures.

Data and Safety Monitoring Board (DSMB) and Data Monitoring Committee (DMC)

The DSMB and the DMC are exactly equivalent. Both refer to a panel of independent experts tasked with carrying out DSM for a given clinical trial. The difference is that the NIH and WHO refer to these panels as DSMBs, whereas the FDA and EMEA prefer to call them DMCs (or DSM Committees, or DSMCs). The following is a general description of a DSMB in a typical National Institutes of Health sponsored clinical trial. Panels in other regulatory contexts operate broadly similarly.

NIH requires DSMBs for large, randomized multisite studies that evaluate treatments intended to prolong life or reduce risk of a major adverse health outcome, such as the rates of mortality or major morbidity. They are generally not required for most other clinical studies. For instance, DSMBs are generally not required for trials at early stages of product development or for

trials addressing lesser outcomes, such as relief of symptoms, unless the trial population is at elevated risk of more severe outcomes.

Unlike the IRB, a DSMB is not a general-purpose, standing committee that concurrently oversees multiple different aspects of multiple studies. Instead, each DSMB is set up *ad hoc* solely to carry out DSM for one particular clinical trial. The exact composition and operation of DSMB depends on the type and complexity of the DSM needed for the given study, and the relevant guidelines of the NIH institute that sponsors the study, and are set forth in the approved protocol. A typical DSMB consists of three to seven voting members with various types of study-relevant expertise and may consist of one or more nonvoting members, such as specialists and *ex officio* invitees, on permanent or *ad hoc* basis.

To carry out the DSM functions it is tasked with, the DSMB meets at specified intervals (and more often if required by the study developments) and reviews the data related to safety and study outcomes. It has considerable leeway in carrying out its DSM functions for the study. Depending on a majority vote of its voting members, the DSMB can review any and all information germane to its DSM functions. Based on its review, it may vote to recommend modifications to, or even the termination of, the study. It can even recommend changes to its own composition and operation in certain ways. For instance, it can recommend adding members in specific areas of expertise. In studies that involve blinding, it can ask to be unblinded fully or partially to any study information as needed.

While the DSMB can make any recommendation it deems appropriate, it does not have the authority to enforce its recommendations. The PI, the sponsor (NIH, in the present example), and other designated parties will be privy to the DSMB's recommendations as set forth in the protocol. Moreover, the IRB and any external regulators with jurisdiction over the study will have *de jure* access. A cognizant official of the sponsoring NIH institute will make the final decision as to whether to accept or modify the DSMB's recommendations and inform the PI and other stakeholders.

Other Mechanisms of External Monitoring

For some studies, external monitoring may be carried out by an Independent Safety Monitor or a sponsor-appointed monitoring committee. However, the use of these mechanisms is uncommon. In most cases, either a full-fledged DSMB or just in-house DSM is used.

DATA AND SAFETY MONITORING BOARD

Data and safety monitoring boards (DSMBs), sometimes referred to as *data monitoring committees*, are groups of experts in relevant disciplines, typically medicine and biostatistics, charged with examination of interim data in an ongoing prospective study, often a randomized clinical trial. DSMBs monitor accumulated safety data such as reported adverse events to determine whether study continuation is reasonable based on acceptable risk versus benefit to participants. DSMBs may also review interim data on efficacy outcomes, with the possibility of recommending early trial stopping under strong evidence of treatment efficacy and/or futility if the study were continued. This entry

describes the composition and operations of a DSMB and provides examples of monitoring activities.

Composition

A DSMB is usually appointed by the study sponsor, which can be an industry entity, foundation, or governmental agency. While very small or low-risk studies may have a single safety monitor, a DSMB typically consists of multiple experts in disciplines relevant to the interventions being examined in the study. Such expertise should include experience with relevant design and analytic approaches; for example, a randomized trial implementing Bayesian response-adaptive randomization would benefit from a DSMB biostatistician experienced with this specific approach. As the DSMB is charged with making recommendations regarding possible trial modifications, including early termination, it is paramount that members are free of actual or perceived conflicts of interest, including personal financial gain given specific trial findings. Members must also agree not to disclose the confidential, sensitive study data reviewed. The sponsor or the DSMB selects a chair to lead meetings and discussions. Decisions are determined by votes among a quorum of DSMB members.

Operating Charter

A DSMB charter, which may be updated during the course of a study, documents DSMB operations including composition, number of members constituting a meeting quorum, anticipated meeting frequency, and specific study data (e.g., safety, efficacy, enrollment, protocol adherence) to be reviewed. For trials with an interim efficacy monitoring component, this document also prespecifies early stopping criteria.

Meeting Frequency

It is desirable for a DSMB to initially convene before a study begins enrollment to review and approve the protocol as well as its specific role and responsibilities as described in the charter. Templates of tables and other study data reports may also be reviewed. For monitoring of interim data, the DSMB should convene frequently enough to assess trial progress and provide feedback to the sponsor in a reasonably timely fashion. However, meeting too frequently may entail review of information that hasn't changed from the previous report, and thus offer little chance of additional useful feedback or a differing conclusion. As an example, for a trial expected to involve several years of recruitment

and follow-up, DSMB meetings twice per year for data review is a potential initial guideline. Scheduled meetings may be skipped or postponed if there are substantial delays or slowdowns in enrollment, and ad hoc meetings added if the DSMB identifies a particular safety issue that it believes warrants additional scrutiny.

Meeting Materials and Structure

Summary materials are usually submitted to a DSMB in report format for review in advance of a meeting. In addition to safety/efficacy analyses, other relevant materials such as recruitment numbers, characteristics of study participants, and protocol adherence, where relevant, are made available for review.

A DSMB meeting, run by the chair, begins with an open session, which the sponsor and study investigators and staff may attend along with the biostatisticians who performed the analyses. In this session, data whose disclosure is appropriate for all study participants are discussed. Along with recruitment, descriptive data, and study conduct, it is often appropriate to discuss adverse reports combined across treatment arms in the open session, as study personnel can respond directly to DSMB members about specific issues raised.

In the closed session, confidential, unblinded data, such as adverse event and efficacy outcome rates reported and compared by treatment arms, are reviewed by the DSMB. Biostatisticians designated as unblinded to study outcomes attend closed sessions to provide any clarifications requested by the DSMB during unblinded data review. The DSMB may then have an executive session for confidential discussions. Written DSMB recommendations, summarized as continuation without modifications, termination, or modification of the study, are reported to and usually accepted by the sponsor, who does have the option to reject or request additional feedback.

A DSMB will determine a trial is acceptable to continue if, in its collective judgment, the risks to participants are acceptable, overall and taking into account relevant potential treatment benefit. Study designs may also specify DSMB actions such as mandatory review or stopping if a given number of particular events are reported.

Interim Efficacy Monitoring

For DSMB review of efficacy outcome data for possible conclusion of superiority of one treatment arm over another, a superiority evidence criterion (typically a probability value comparing primary efficacy outcome

between arms using available data) is compared to a prespecified stopping boundary. If this boundary is crossed, the DSMB will usually recommend stopping the trial and concluding efficacy of a treatment arm. Rarely, special circumstances (e.g., concerns about benefit versus risk, skepticism about early treatment effect magnitude) may lead a DSMB to delay stopping despite crossing of a monitoring boundary, with stopping reconsidered after efficacy data from additional participants, or perhaps additional requested supporting data, are reviewed. However, a DSMB is usually expected to adhere to prespecified stopping boundaries because deviations can affect a trial's operating characteristics including Type I error and power.

Some trial designs incorporate DSMB monitoring for futility, where available efficacy data indicate that the trial, if continued to planned sample size, has a low chance of reporting a statistically significant efficacy finding. This can occur if the observed treatment effect is lower, and/or has substantially more variability in its estimate, than expected during study design. As for superiority monitoring, futility monitoring frequencies and stopping parameters (boundaries based on probability values or conditional power criteria) must be fully prespecified in the DSMB charter.

Individual study designs may include additional DSMB responsibilities based on interim data review, such as approving additional cohorts in a dose-finding study or approving sample size modifications. Such monitoring should again be fully prespecified and preserve statistical integrity of the study.

DATA CLEANING

Data cleaning, or *data cleansing*, is an important part of the process involved in preparing data for analysis. Data cleaning is a subset of *data preparation*, which

also includes scoring tests, matching data files, selecting cases, and other tasks that are required to prepare data for analysis.

Missing and erroneous data can pose a significant problem to the reliability and validity of study outcomes. Many problems can be avoided through careful survey and study design. During the study, watchful monitoring and data cleaning can catch problems while they can still be fixed. At the end of the study, multiple imputation procedures may be used for data that are truly irretrievable.

The opportunities for data cleaning are dependent on the study design and data collection methods. At one extreme is the anonymous web survey, with limited recourse in the case of errors and missing data. At the other extreme are longitudinal studies with multiple treatment visits and outcome evaluations. Conducting data cleaning during the course of a study allows the research team to obtain otherwise missing data and can prevent costly data cleaning at the end of the study. This entry discusses problems associated with data cleaning and their solutions.

Types of “Dirty Data”

Two types of problems are encountered in data cleaning: missing data and errors. The latter may be the result of respondent mistakes or data entry errors. The presence of “dirty data” reduces the reliability and validity of the measures. If responses are missing or erroneous, they will not be reliable over time. Because reliability sets the upper bound for validity, unreliable items reduce validity.

Missing Data

Missing data reduce the sample size available for the analyses. An investigator’s research design may require 100 respondents in order to have sufficient power to test the study hypotheses. Substantial effort may be required to recruit and treat 100 respondents. At the end of the study, if there are 10 important variables, with each variable missing only 5% of the time, the investigator may be reduced to 75 respondents with complete data for the analyses. Missing data effectively reduce the power of the study. Missing data can also introduce bias because questions that may be embarrassing or reveal anything illegal may be left blank. For example, if some respondents do not answer items about income, place of birth (for immigrants without documents), or drug use, the remaining cases with complete data are a biased sample that is no longer representative of the population.

Data Errors

Data errors are also costly to the study because lowered reliability attenuates the results. Respondents may make mistakes, and errors can be introduced during data entry. Data errors are more difficult to detect than missing data. Table 1 shows examples of missing data (ethnicity, income), incomplete data (date and place of birth), and erroneous data (sex).

Causes

All measuring instruments are flawed, regardless of whether they are in the physical or social sciences. Even with the best intentions, everyone makes errors. In the social sciences, most measures are self-report. Potentially embarrassing items can result in biased responses. Lack of motivation is also an important source of error. For example, respondents will be highly motivated in high-stakes testing such as the College Board exams but probably do not bring the same keen interest to one’s research study.

Solutions and Approaches

Data problems can be prevented by careful study design and by pretesting of the entire research protocol. After the forms have been collected, the task of data cleaning begins. The following discussion of data cleaning is for a single paper-and-pencil survey collected in person. Data cleaning for longitudinal studies, institutional data sets, and anonymous surveys is addressed in a later section.

Missing Data

The best approach is to fill in missing data as soon as possible. If a data collection form is skimmed when it is collected, the investigator may be able to ask questions at that time about any missing items. After the data are entered, the files can be examined for remaining missing values. In many studies, the team may be able to contact the respondent or fill in basic data from memory. Even if the study team consists of only the principal investigator, it is much easier to fill in missing data after an interview than to do so a year later. At that point, the missing data may no longer be retrievable.

Data Entry Errors

A number of helpful computer procedures can be used to reduce or detect data entry errors, such as double entry or proactive database design. Double entry refers to entering the data twice, in order to ensure accuracy. Careful database design includes

Table 1 Data Errors and Missing Data

<i>Variable</i>	<i>“True” Data</i>	<i>Incomplete, Incorrect, or Missing Data</i>
Name	Maria Margaret Smith	Maria Smith
Date of birth	2/19/1981	1981
Sex	F	M
Ethnicity	Hispanic and Caucasian	
Education	B.A., Economics	College
Place of birth	Nogales, Sonora, Mexico	Nogales
Annual income	\$50,000	

structured data entry screens that are limited to specified formats (dates, numbers, or text) or ranges (e.g., sex can only be M or F, and age must be a number less than 100).

Perils of Text Data

Text fields are the default for many database management systems, and a new user may not be aware of the problems that text data can cause at the end of a project. For example, “How many days did you wait before you were seen by a physician?” should require a number. If the database allows text data, the program will accept “10,” “ten days,” “10 days,” “5 or 6,” “half a day,” “2–3,” “about a month,” “not sure,” “NA,” and so on. Before analysis can proceed, every one of these answers must be converted to a number. In large studies, the process of converting text to numbers can be daunting. This problem can be prevented by limiting fields to numeric inputs only.

Logically Impossible Responses

Computer routines can be used to examine the data logically and identify a broad range of errors. These validation routines can detect out-of-range values and logical inconsistencies; there are some combinations that are not possible in a data set. For example, all the dates for data collection should fall between the project’s starting date and ending date. In a study of entire families, the children should be younger than their parents, and their ages should be somewhat consistent with their reported grade levels. More sophisticated procedures, such as Rasch modeling techniques, can be used to identify invalid surveys submitted by respondents

who intentionally meddled with the system (for example, by always endorsing the first response).

Logistics

The amount of time required for data cleaning is dependent on who cleans the data and when the data cleaning takes place. The best people to clean the data are the study team, and the best time is while the study is under way. The research staff is familiar with the protocol and probably knows most of the study participants. A data set that is rife with problems can require a surprising amount of time for data cleaning at the end of a study.

Longitudinal Studies and Other Designs

Anonymous surveys, secondary data sets, longitudinal studies with multiple forms collected on multiple occasions, and institutional databases present different data-cleaning problems and solutions.

Anonymous surveys provide few opportunities for data cleaning. It is not possible to ask the respondent to complete the missing items. Data cleaning will be limited to logic checks to identify inconsistent responses and, in some cases, using the respondent’s answers to other questions.

Secondary data sets, such as those developed and maintained by the Centers for Disease Control and Prevention, will be fully documented, with online files for the data collection forms, research protocols, and essential information about data integrity. The data collection instruments have been designed to minimize errors, and the majority of possible data cleaning will be complete.

Institutional databases can be an excellent source of information for addressing research questions. Hospital billing and claims files and college enrollment records have often been in place for decades. However, these systems were designed to meet an institution’s ongoing requirements and were rarely planned with one’s research study in mind. *Legacy databases* present some unique challenges for data cleaning.

In contrast to secondary data analyses, institutional databases may have limited documentation available to the outside researcher. Legacy databases usually change in order to meet the needs of the institution. The records of these changes may be unavailable or difficult for nonprogrammers to follow. User-initiated changes may be part of the institutional lore. Data accuracy may be high for critical data fields but lower for other variables, and a few variables may be entirely blank. Variable formats may change across data files or tables. For example, the same item in three data sets may have

different field characteristics, with a leading space in the first, a leading zero in the second, and neither in the third. Data-cleaning approaches may involve significant time examining the data. The accuracy of the final product will need to be verified with knowledgeable personnel.

Studies with multiple instruments allow the investigators to reconstruct additional missing and erroneous data by triangulating data from the other instruments. For example, one form from a testing battery may be missing a date that can be inferred from the rest of the packet if the error is caught during data entry.

Longitudinal studies provide a wealth of opportunity to correct errors, provided early attention to data cleaning and data entry have been built into the study. Identification of missing data and errors while the respondent is still enrolled in the study allows investigators to “fill in the blanks” at the next study visit. Longitudinal studies also provide the opportunity to check for consistency across time. For example, if a study collects physical measurements, children should not become shorter over time, and measurements should not move back and forth between feet and meters.

Along with opportunities to catch errors, studies with multiple forms and/or multiple assessment waves also pose problems. The first of these is the file-matching problem. Multiple forms must be matched and merged via computer routines. Different data files or forms may have identification numbers and sorting variables that do not exactly match, and these must be identified and changed before matching is possible.

Documentation

Researchers are well advised to keep a log of data corrections in order to track changes. For example, if a paper data collection form was used, the changes can be recorded on the form, along with date the item was corrected. Keeping a log of data corrections can save the research team from trying to clean the same error more than once.

Data Integrity

Researcher inexperience and the ubiquitous lack of resources are the main reasons for poor data hygiene. First, experience is the best teacher, and few researchers have been directly responsible for data cleaning or data stewardship. Second, every study has limited resources. At the beginning of the study, the focus will invariably be on developing data collection forms and study

recruitment. If data are not needed for annual reports, they may not be entered until the end of the study. The data analyst may be the first person to actually see the data. At this point, the costs required to clean the data are often greater than those required for the actual analyses.

Data Imputation

At the end of the data-cleaning process, there may still be missing values that cannot be recovered. These data can be replaced using data imputation techniques. *Imputation* refers to the process of replacing a missing value with a reasonable value. Imputation methods range from mean imputation (replacing a missing data point with the average for the entire study) to *hot deck imputation* (making estimates based on a similar but complete data set), *single imputation* if the proportion of missing values is small, and *multiple imputation*. Multiple imputation remains the best technique and will be necessary if the missing data are extensive or the values are not missing at random. All methods of imputation are considered preferable to case deletion, which can result in a biased sample.

DATA MINING

Modern researchers in various fields are confronted by an unprecedented wealth and complexity of data. However, the results available to these researchers through traditional data analysis techniques provide only limited solutions to complex situations. The approach to the huge demand for the analysis and interpretation of these complex data is managed under the name of data mining or *knowledge discovery*. *Data mining* is defined as the process of extracting useful information from large data sets through the use of any relevant data analysis techniques developed to help people make

better decisions. These data mining techniques themselves are defined and categorized according to their underlying statistical theories and computing algorithms. This entry discusses these various data mining methods and their applications.

Types of Data Mining

In general, data mining methods can be separated into three categories: *unsupervised learning*, *supervised learning*, and *semisupervised learning methods*. Unsupervised methods rely solely on the input variables (predictors) and do not take into account output (response) information. In unsupervised learning, the goal is to facilitate the extraction of implicit patterns and elicit the natural groupings within the data set without using any information from the output variable. On the other hand, supervised learning methods use information from both the input and output variables to generate the models that classify or predict the output values of future observations. The semisupervised method mixes the unsupervised and supervised methods to generate an appropriate classification or prediction model.

Unsupervised Learning Methods

Unsupervised learning methods attempt to extract important patterns from a data set without using any information from the output variable. *Clustering analysis*, which is one of the unsupervised learning methods, systematically partitions the data set by minimizing within-group variation and maximizing between-group variation. These variations can be measured on the basis of a variety of distance metrics between observations in the data set. Clustering analysis includes hierarchical and nonhierarchical methods.

Hierarchical clustering algorithms provide a dendrogram that represents the hierarchical structure of clusters. At the highest level of this hierarchy is a single cluster that contains all the observations, while at the lowest level are clusters containing a single observation. Examples of hierarchical clustering algorithms are *single linkage*, *complete linkage*, *average linkage*, and *Ward's method*.

Nonhierarchical clustering algorithms achieve the purpose of clustering analysis without building a hierarchical structure. The *k-means clustering algorithm* is one of the most popular nonhierarchical clustering methods. A brief summary of the *k-means clustering algorithm* is as follows: Given k seed (or starting) points, each observation is assigned to one of the k seed points close to the observation, which creates k clusters. Then, seed points are replaced with the mean of the currently assigned clusters. This procedure is repeated with updated

seed points until the assignments do not change. The results of the *k-means clustering algorithm* depend on the distance metrics, the number of clusters (k), and the location of seed points. Other nonhierarchical clustering algorithms include *k-medoids* and *self-organizing maps*.

Principal components analysis (PCA) is another unsupervised technique and is widely used, primarily for dimensional reduction and visualization. PCA is concerned with the covariance matrix of original variables, and the eigenvalues and eigenvectors are obtained from the covariance matrix. The product of the eigenvector corresponding to the largest eigenvalue and the original data matrix leads to the first principal component (PC), which expresses the maximum variance of the data set. The second PC is then obtained via the eigenvector corresponding to the second largest eigenvalue, and this process is repeated N times to obtain N PCs, where N is the number of variables in the data set. The PCs are uncorrelated to each other, and generally, the first few PCs are sufficient to account for most of the variations. Thus, the PCA plot of observations using these first few PC axes facilitates visualization of high-dimensional data sets.

Supervised Learning Methods

Supervised learning methods use both the input and output variables to provide the model or rule that characterizes the relationships between the input and output variables. Based on the characteristics of the output variable, supervised learning methods can be categorized as either *regression* or *classification*. In regression problems, the output variable is continuous, so the main goal is to predict the outcome values of an unknown future observation. In classification problems, the output variable is categorical, and the goal is to assign existing labels to an unknown future observation.

Linear regression models have been widely used in regression problems because of their simplicity. Linear regression is a parametric approach that provides a linear equation to examine relationships of the mean response to one or to multiple input variables. Linear regression models are simple to derive, and the final model is easy to interpret. However, the parametric assumption of an error term in linear regression analysis often restricts its applicability to complicated multivariate data. Further, linear regression methods cannot be employed when the number of variables exceeds the number of observations. *Multivariate adaptive regression spline* (MARS) is a nonparametric regression method that compensates for limitation of ordinary regression models. MARS is one of the few tractable methods for high-dimensional problems with interactions, and it estimates a completely unknown

relationship between a continuous output variable and a number of input variables. MARS is a data-driven statistical linear model in which a forward stepwise algorithm is first used to select the model term and is then followed by a backward procedure to prune the model. The approximation bends at “knot” locations to model curvature, and one of the objectives of the forward stepwise algorithm is to select the appropriate knots. Smoothing at the knots is an option that may be used if derivatives are desired.

Classification methods provide models to classify unknown observations according to the existing labels of the output variable. Traditional classification methods include *linear discriminant analysis* (LDA) and *quadratic discriminant analysis* (QDA), based on Bayesian theory. Both LDA and QDA assume that the data set follows normal distribution. LDA generates a linear decision boundary by assuming that populations of different classes have the same covariance. QDA, on the other hand, does not have any restrictions on the equality of covariance between two populations and provides a quadratic equation that may be efficient for linearly nonseparable data sets.

Many supervised learning methods can handle both regression and classification problems, including decision trees, *support vector machines* (SVMs), *k-nearest neighbors* (kNNs), and *artificial neural networks* (ANNs). *Decision tree models* have gained huge popularity in various areas because of their flexibility and interpretability. Decision tree models are flexible in that the models can efficiently handle both continuous and categorical variables in the model construction. The output of decision tree models is a hierarchical structure that consists of a series of if-then rules to predict the outcome of the response variable, thus facilitating the interpretation of the final model. From an algorithmic point of view, the decision tree model has a forward stepwise procedure that adds model terms and a backward procedure for pruning, and it conducts variable selection by including only useful variables in the model. SVM is another supervised learning model popularly used for both regression and classification problems. SVMs use geometric properties to obtain a separating hyperplane by solving a convex optimization problem that simultaneously minimizes the generalization error and maximizes the geometric margin between the classes. Nonlinear SVM models can be constructed from kernel functions that include linear, polynomial, and radial basis functions. Another useful supervised learning method is kNNs. A type of *lazy-learning* (*instance-based learning*) technique, kNNs do not require a trained model. Given a query point, the k closest points are determined. A variety of distance measures can be applied to calculate how close each

point is to the query point. Then, the k nearest points are examined to find which of the categories belong to the k nearest points. Last, this category is assigned to the query point being examined. This procedure is repeated for all the points that require classification. Finally, ANNs, inspired by the way biological nervous systems learn, are widely used for prediction modeling in many applications. ANN models are typically represented by a network diagram containing several layers (e.g., input, hidden, and output layers) that consist of nodes. These nodes are interconnected with weighted connection lines whose weights are adjusted when training data are presented to the ANN during the training process. The neural network training process is an iterative adjustment of the internal weights to bring the network's output closer to the desired values through minimizing the mean squared error.

Semisupervised Learning Methods

Semisupervised learning approaches have received increasing attention in recent years. Olivier Chapelle and his coauthors (2006) described semisupervised learning as “halfway between supervised and unsupervised learning” (p. 4). Semisupervised learning methods create a classification model by using partial information from the labeled data. One-class classification is an example of a semisupervised learning method that can distinguish between the class of interest (target) and all other classes (outlier). In the construction of the classifiers, one-class classification techniques require only the information from the target class. The applications of one-class classification include *novelty detection*, *outlier detection*, and *imbalanced classification*.

Support vector data description (SVDD) is a one-class classification method that combines a traditional SVM algorithm with a density approach. SVDD produces a classifier to separate the target from the outliers. The decision boundary of SVDD is constructed from an optimization problem that minimizes the volume of the hypersphere from the boundary and maximizes the target data being captured by the boundary. The main difference between the supervised and semisupervised classification methods is that the former generates a classifier to classify an unknown observation into the predefined classes, whereas the latter gives a closed-boundary around the target data in order to separate them from all other types of data.

Applications

Interest in data mining has increased greatly because of the availability of new analytical techniques with the

potential to retrieve useful information or knowledge from vast amounts of complex data that were heretofore unmanageable. Data mining has a range of applications, including manufacturing, marketing, telecommunication, health care, biomedicine, e-commerce, and sports. In manufacturing, data mining methods have been applied to predict the number of product defects in a process and identify their causes. In marketing, market basket analysis provides a way to understand the behavior of profitable customers by analyzing their purchasing patterns. Further, unsupervised clustering analyses can be used to segment customers by market potential. In the telecommunication industries, data mining methods help sales and marketing people establish loyalty programs, develop fraud detection modules, and segment markets to reduce revenue loss. Data mining has received tremendous attention in the field of bioinformatics, which deals with large amounts of high-dimensional biological data. Data mining methods combined with *microarray technology* allow monitoring of thousands of genes simultaneously, leading to a greater understanding of molecular patterns. Clustering algorithms use microarray gene expression data to group the genes based on their level of expression, and classification algorithms use the labels of experimental conditions (e.g., disease status) to build models to classify different experimental conditions.

Data Mining Software

A variety of data mining software is available. SAS Enterprise Miner (www.sas.com), SPSS (an IBM company) Clementine (www.spss.com), and S-PLUS Insightful Miner (www.insightful.com) are examples of widely used commercial data mining software. In addition, commercial software developed by Salford Systems (www.salford-systems.com) provides CART, MARS, TreeNet, and Random Forests for specialized uses of tree-based models. Free data mining software packages also are available. These include RapidMiner (rapid-i.com), Weka (www.cs.waikato.ac.nz/ml/weka), and R (www.r-project.org).

DATA SHARING REPOSITORIES

Data sharing repositories, which store and/or manage access to clinical research data, enable independent investigators to request and use previously collected data for scientific purposes. Each year, hundreds of thousands of clinical studies are initiated and completed, characterizing diseases, testing new interventions, and determining the best treatments for patients. For each one of these clinical studies, a vast amount of data are produced, including the raw clinical study data (i.e., individual participant-level data [IPD]), summary-level data (i.e., reports summarizing the study—like a journal publication), and the accompanying study documentation. Although the summary results from clinical studies are typically disseminated through peer-reviewed publications or on clinical trial registration and results reporting platforms, such as ClinicalTrials.gov, a large amount of study data remain unavailable to the research community. In particular, selective and incomplete publication of study results undermines the ability of patients, physicians, funders, and policy makers to make informed decisions about the safety and efficacy of interventions. However, as widespread awareness of the importance of research transparency has grown, there have been efforts to promote the sharing of clinical study data. This entry discusses the value of sharing clinical research data, provides an overview of prominent data sharing repositories, outlines examples of how data sharing has influenced practice and policy, and presents opportunities to further facilitate clinical study data sharing.

The Value of Data Sharing

Since the early 2000s, there has been an increased awareness of the importance of research transparency among the scientific community. Studies have consistently outlined concerns about the number of clinical research findings that are selectively or incompletely reported in the literature. Moreover, given that only a limited portion of all collected data are actually analyzed and reported, there is a greater potential that can be achieved through the sharing of clinical study data and supporting documentation,

Table 1 Common Supporting Documents Available on Data Sharing Repositories

<i>Type of Document</i>	<i>Information Provided</i>	<i>Potential Uses</i>
Clinical study report (CSR)	CSRs are typically written for regulators (e.g., Food and Drug Administration European Medicines Agency) and often follow industry guidelines. These documents can contain efficacy evaluations, safety evaluations, trial protocols, SAPs, and CRFs. Compared to publications, CSRs contain more detailed descriptions of the design, conduct, and results from trials.	CSRs and study protocols increase transparency by allowing for the appraisal of study design and reporting characteristics. For instance, they can provide information that is not included in the methods or results sections of publications (e.g., the outcomes necessary for systematic reviews and/or meta-analyses).
Protocol and protocol amendments	Protocols describe the study objectives, design characteristics, methods, and statistical considerations.	
Case report forms (CRFs)	CRFs are questionnaires used by clinical trial sponsors to record information about each trial participant.	CRFs can be used to ensure the accuracy of the reported data.
Statistical analysis plan (SAP)	SAPs provide a complete description of the methods used during data collection, analysis, interpretation, presentation, and organization.	SAPs allow independent investigators to evaluate more detailed characteristics of the statistical methodology, including statistical power calculations.
Individual case safety report (ICSR)	ICSRs provided detailed information related to adverse reactions that may occur among study subjects.	ICSRs allow investigators to identify potential adverse events that may not be reported in publications or on clinical trial registration and results reporting platforms.
Individual patient-level data (IPD)	IPDs are the individual data recorded for each participant in a clinical study, such as age, gender, race, efficacy outcomes, laboratory results, and so on.	IPD can be used to identify additional outcomes over a longer period of follow-up, conduct time-to-event analyses inform risk of bias evaluations check the validity of previously reported findings standardize units of analyses conduct more complex analyses account for a wider range of covariates answer secondary clinical questions and/or explore prognostic factors and surrogate outcomes.

which contain substantially more information than published articles and trial registration and reporting platforms (Table 1). Sharing maximizes the value of collected data by allowing external researchers to evaluate the validity of findings, conduct secondary analyses of unexamined outcomes or data, and perform systematic reviews and meta-analyses utilizing IPD. In addition to uncovering new insights that can be used to inform future research endeavors, data sharing minimizes duplicative research, leading to reduced research costs and a lower burden on study participants.

To promote the sharing of individual and aggregate-level data, many key clinical research stakeholders have outlined data sharing recommendations or policies, including the National Academy of Medicine (formerly

the Institute of Medicine), the World Health Organization (WHO), the U.S. National Institutes of Health (NIH), the European Clinical Research Infrastructure Network, the International Committee for Medical Journal Editors, the Pharmaceutical Research and Manufacturers of America, the European Federation of Pharmaceutical Industries and Associations, and various funders (e.g., Bill & Melinda Gates Foundation the Patient-Centered Outcomes Research Institute). For instance, in 2015, the National Academy of Medicine recommended that researchers should share the analyzable data and supporting documentation within 18 months of completing a clinical study and advocated to change the culture of clinical research to embrace data sharing.

While there are a number of different methods that can be used to share research data, including online supplementary materials or individual data repositories (e.g., osf.io), IPD requires sharing in a responsible manner that protects patient privacy and is consistent with informed consent. Research participants, researchers, and sponsors have expressed concerns about attempts to reidentify patient information, the use of shared data to conduct inappropriate secondary analyses, and access to intellectual property and commercial confidential information. However, data sharing repositories minimize these concerns and are attentive to stakeholder needs by facilitating the responsible sharing of clinical study data.

Clinical Data Sharing Repositories

There are a number of prominent clinical study data sharing repositories that provide controlled access to IPD and study documentation (Table 2). While certain repositories store the data that they make available, other repositories, such as the Yale Open Access Data (YODA) Project, act as a facilitator between data requestors and data generators. However, a common characteristic across these data repositories is that they promote responsible conduct by providing access to de-identified data to qualified researchers who have submitted data requests describing clear research objectives and methods (Table 3). By requiring data requestors to agree not to use, copy, or transmit data in a manner outside of the outlined scope, these data sharing repositories protect the privacy and confidentiality of research participants. Here, the characteristics of a number of prominent data sharing repositories are outlined.

Biological Specimen and Data Repository Information Center (BioLINCC): A Government-Run Repository

Since 2000, the National Heart, Lung, and Blood Institute (NHLBI) of the NIH has shared de-identified IPD with the scientific community. After a proprietary-use period, researchers conducting NHLBI-funded clinical trials and prospective cohort studies are required to store and share their data in the BioLINCC repository. Using BioLINCC, external investigators can then request study data by providing a description of their project and evidence of approval by the institutional review board or ethics committee at their institution. Once investigators sign a data-use agreement (Table 3), they receive access to the data for a 3-year period.

ClinicalStudyDataRequest.com (CSDR): An Industry-Run Repository

CSDR, a consortium of clinical study sponsors that was launched in 2013, allows independent investigators to request data from approximately 3,000 clinical studies conducted by over a dozen data contributors, the majority of which are pharmaceutical companies. Independent investigators can use the CSDR website to submit detailed research proposals outlining how the data that they are requesting will be used (Table 3). Although the research proposals are initially evaluated by an independent review panel, which is run by the Wellcome Trust, study sponsors have the opportunity to approve or reject submissions during the second stage of review.

Academic and Nonprofit-Run Repositories

The YODA Project, an initiative founded in 2011 and housed within Yale University, facilitates access to clinical trial data. The YODA Project first partnered with Medtronic, Inc., to solicit independent analyses of IPD from certain trials, and since 2014, 2015, and 2017, Johnson & Johnson has shared clinical trial data from pharmaceutical products, medical devices, and consumer products, respectively. The YODA Project uses a *trusted intermediary* or *neutral broker* system, whereby YODA Project affiliates have full authority and independence to make decisions regarding the approval or rejection of data requests, which must demonstrate a clear basis of scientific merit and outline how the research will contribute to scientific knowledge and public health. This system helps maintain independence between data generators and data requestors.

In 2014, Bristol-Myers Squibb (BMS) and the Duke Clinical Research Institute (DCRI) partnered to create the Supporting Open Access for Researchers, a repository dedicated to sharing clinical information for BMS drugs approved by the United States or Europe. Similar to the YODA Project, faculty from DCRI review and approve all data requests. In 2018, the nonprofit organization Vivli launched a global clinical research data sharing platform intended to coordinate existing repositories.

The Impact of Data Sharing Repositories

Although many clinical data sharing repositories are relatively new, the findings from analyses utilizing shared data have already had an impact on policies, guidelines, and clinical care. In 1997, the Digitalis Investigation Group (DIG) group published the results from a federally funded trial of 6,800 stable patients

Table 2 Prominent Clinical Data Sharing Repositories

<i>Name</i>	<i>Program Description</i>	<i>Data Partners</i>	<i>Available Studies^a</i>
The Yale Open Data Access Project	Academic-based data sharing program run through Yale University	Johnson & Johnson Medtronic, Inc. Queen Mary University of London SI-BONE, Inc.	403
Supporting Open Access to Researchers—Bristol-Myers Squibb	Academic-based data sharing program run through the Duke Clinical Research Institute	Bristol-Myers Squibb Duke	Unclear: drugs approved after January 2008 in the United States and/or Europe
Vivli—Center for Global Clinical Research Data	Independent nonprofit organization that evolved from a project at the Multi-Regional Clinical Trials Center of Brigham and Women's Hospital and Harvard	Abbvie, Biogen, BioLINCC, Boehringer Ingelheim, Celgene, Critical Path Institute, Cure Duchenne, Daiichi-Sankyo, Doris Duke Charitable Foundation, Duke University, GlaxoSmithKline (GSK), Harvard University, IMMPort, Johns Hopkins University, Johnson & Johnson, Lilly, Pfizer, Project Data Sphere, Regeneration, Roche, Takeda, Tempus, the Leona M. and Harry B. Helmsley Charitable Trust, UCB, and University of California, San Francisco	5,422
ClinicalStudyData Request.com	Consortium of clinical study sponsors and funders	Astellas, Bayer, Chungai, Eisai, GlaxoSmithKline, Novartis, Ono, Roche, Sanofi, Shionogi, DSP/Sunovion, UCB, ViiV, Cancer Research UK	2,962
Project Data Sphere	Independent nonprofit initiative of the CEO Roundtable on Cancer	Alliance for Clinical Trials in Oncology, Amgen, AstraZeneca, Bayer, Celgene Corporation, Clovis Oncology, ECOG-ACRIN Cancer Research Group, EMD Serono, Janssen Research & Development, Madrigal Pharmaceuticals, National Cancer Institute (National Institutes of Health), Pfizer, Sanofi, Takeda	155
Biological Specimen and Data Repository Information Coordinating Center (BioLINCC)	Data repository run by the National Heart, Lung and Blood Institute, a center at the National Institutes of Health	Clinical study of biospecimens and clinical study data	227

^aStudies available as of June 2020.

Table 3 Common Data Request Components

Category	Components
Primary investigator	Name, degree(s), primary affiliation, contact information, email address, funding and conflict of interest disclosures
Key personnel	Names, degrees
Research proposal	Project title narrative summary scientific abstract specific aims project purpose research methods software to be used inclusion/exclusion criteria outcome measure predictor/ independent variable statistical analysis plan project time line dissemination plan
Institutional Review Board or Committee Review	Data sets may only be released to researchers who are under the oversight of an Institutional Review Board
Data Use Agreement/ Research Materials Distribution Agreement	Requestors must sign an agreement prior to receiving data, which outlines the stipulations and requirements of the data request

with heart failure who were randomized to digoxin or placebo. The study findings, which were included in clinical guidelines, suggested that digoxin decreased the risk of hospitalization for worsening heart failure and did not reduce mortality for both men and women. However, after the IPD were made available through NHLBI, independent researchers were able to conduct sex-based subgroup analyses demonstrating that digoxin was actually associated with a higher risk of death and a smaller reduction in the rate of hospitalization for worsening heart failure among women. This study was only one of many secondary analyses conducted using the shared DIG trial data.

Another example of the success of data sharing was the Systolic Blood Pressure Intervention Trial (SPRINT). As part of *New England Journal of Medicine's* 2017 "Aligning Incentives for Sharing Clinical Trial Data" summit, the journal hosted the SPRINT Data Analysis Challenge, which shared SPRINT data to encourage a wide range of novel

secondary analyses. A large number of analyses were conducted, addressing a variety of questions, and one of the key findings was that the originally published SPRINT study incorrectly calculated data for the Framingham 10-year cardiovascular risk score regression model.

In 2017, a systematic review of new evidence on the use of bedaquiline was released, which was used to inform changes in the WHO interim policy guidance on the use of bedaquiline for the treatment of multidrug-resistant tuberculosis (MDR-TB). Using data obtained through the YODA Project, the authors found bedaquiline effective for treatment of MDR-TB.

Outstanding Issues

Despite the success of prominent clinical data sharing platforms, outstanding issues remain to be addressed. First, it will be necessary to develop a sustainable model that covers the cost of preparing, storing, and sharing clinical research data. To date, the majority of the clinical data sharing repositories have received funding from industry and the U.S. federal government. The costs associated with data sharing can undermine the sharing of older data, which may exist in legacy data systems or the data collected by academia. To enable data sharing going forward, sponsors should incorporate the costs to prepare data, store data, and review data sharing requests into any future research funding. Second, there is a need to develop and adopt data format standards, including standardized informed consent language and expectations outlining how long shared data will be made available. Improvements in these areas will make it easier for researchers to request and use existing data. Lastly, various stakeholders have outlined concerns about patient privacy breaches or data that are used for misleading or inappropriate analyses. However, there is little evidence to support these concerns. Therefore, further increasing awareness of existing data sharing repositories, including clarifications of how data sharing repositories protect patient privacy, is warranted.

Despite these challenges, data sharing repositories support a culture that promotes research transparency. As data sharing repositories continue to develop, and clinical data sharing becomes the norm, the research community, as well as patient care, will benefit from the resources saved and the high-quality research findings that are generated through these efforts.

DATA SNOOPING

The term *data snooping*, sometimes also referred to as *data dredging* or *data fishing*, is used to describe the situation in which a particular data set is analyzed repeatedly without an a priori hypothesis of interest.

The practice of data snooping, although common, is problematic because it can result in a significant finding (e.g., rejection of a null hypothesis) that is nothing more than a chance artifact of the repeated analyses of the data. The biases introduced by data snooping increase the more a data set is analyzed in the hope of a significant finding. Empirical research that is based on experimentation and observation has the potential to be impacted by data snooping.

Data Snooping and Multiple Hypothesis Testing

A hypothesis test is conducted at a significance level, denoted α , corresponding to the probability of incorrectly rejecting a true null hypothesis (the so-called Type 1 error). Data snooping essentially involves performing a large number of hypothesis tests on a particular data set with the hope that one of the tests will be significant. This data-snooping process of performing a large number of hypothesis tests results in the actual significance level being increased, or the burden of proof for finding a significant result being substantially reduced, resulting in potentially misleading results. For example, if 100 independent hypothesis tests are conducted on a data set at a significance level of 5%, it would be expected that about 5 out of the 100 tests would yield significant results simply by chance alone, even if the null hypothesis were, in fact, true. Any conclusions of statistical significance at the 5% level based on an analysis such as this are misleading because the data-snooping process has essentially ensured that something significant will be found. This means that if new data are obtained, it is unlikely that the “significant” results found via the data-snooping process would be replicated.

Data-Snooping Examples

Example 1

An investigator obtains data to investigate the impact of a treatment on the mean of a response variable of interest without a predefined view (alternative hypothesis) of the direction (positive or negative) of the possible effect of the treatment. Data snooping would occur in this situation if after analyzing the data, the investigator observes that the treatment appears to have a negative effect on the response variable and then uses a one-sided alternative hypothesis corresponding to the treatment having a negative effect. In this situation, a two-sided alternative hypothesis, corresponding to the investigator's a priori ignorance on the effect of the treatment, would be appropriate. Data snooping in this

example results in the p value for the hypothesis test being halved, resulting in a greater chance of assessing a significant effect of the treatment. To avoid problems of this nature, many journals require that two-sided alternatives be used for hypothesis tests.

Example 2

A data set containing information on a response variable and six explanatory variables is analyzed, without any a priori hypotheses of interest, by fitting each of the 64 multiple linear regression models obtained by means of different combinations of the six explanatory variables, and then only statistically significant associations are reported. The effect of data snooping in this example would be more severe than in Example 1 because the data are being analyzed many more times (more hypothesis tests are performed), meaning that one would expect to see a number of significant associations simply due to chance.

Correcting for Data Snooping

The ideal way to avoid data snooping is for an investigator to verify any significant results found via a data-snooping process by using an independent data set. Significant results not replicated on the independent data set would then be viewed as spurious results that were likely an artifact of the data-snooping process. If an independent data set is obtainable, then the initial data-snooping process may be viewed as an initial exploratory analysis used to inform the investigator of hypotheses of interest. In cases in which an independent data set is not possible or very expensive, the role of an independent data set can be mimicked by randomly dividing the original data into two smaller data sets: one half for an initial exploratory analysis (the *training set*) and the other half for validation (the *validation set*). Due to prohibitive cost and/or time, obtaining an independent data set or a large enough data set for dividing into training and validation sets may not be feasible. In such situations, the investigator should describe exactly how the data were analyzed, including the number of hypothesis tests that were performed in finding statistically significant results, and then report results that are adjusted for multiple hypothesis-testing effects. Methods for adjusting for multiple hypothesis testing include the *Bonferroni correction*, *Scheffé's method*, *Tukey's test*, and more recently the *false discovery rate*. The relatively simple Bonferroni correction works by conducting individual hypothesis tests at level of significance α/g where g is the number of hypothesis tests carried out. Performing the individual hypothesis tests at level of significance α/g provides a

crude means of maintaining an overall level of significance of at least α . Model averaging methods that combine information from every analysis of a data set are another alternative for alleviating the problems of data snooping.

Data mining, a term used to describe the process of exploratory analysis and extraction of useful information from data, is sometimes confused with data snooping. Data snooping is sometimes the result of the misuse of data-mining methods, such as the framing of specific alternative hypotheses in response to an observation arising out of data mining.

DATA VISUALIZATION

Interacting with data visualizations is a daily routine for many people. Once limited to scholarly circles, visualizations have become a mainstay for presenting information on the internet and in popular media. Beyond that, computers, tablets, smartphones, and wearable technology have put visualizations in front of people on an ongoing basis while also making them more personalized (e.g., tracking step counts, heart rates, and screen time). The growth of data visualization into every corner of people's lives should provoke reflection about why these tools have become so ubiquitous, when and how researchers should employ them, and how researchers can engage in visualization practices in an ethical and responsible manner. This entry presents a brief history of data visualization, considers the best practices of creating and utilizing data visualizations, and highlights the tools and various forms of data visualization available to researchers when using qualitative or quantitative research methods.

History of Data Visualization

The researcher who engages in data visualization is joining a long and rich historical tradition. The earliest known examples of data visualization—carved maps and star charts painted on cave walls—date back to the prehistoric period. Progressive developments in observing and representing the stars yielded advancements in stellar navigation, enabling trade and exploration. In the premodern era, Chinese cartographers pioneered developments in mapmaking and early attempts at rendering 3D forms, such as topographical maps. Improvements in instrumentation extending from the Islamic Golden Age (c. 800–1258 CE) into the Enlightenment Era in Europe (c. 1750–1789) further allowed for the collection of more and better data, rendering visualization more practical as a tool for presenting data in a concise way.

Several innovations emerged from data analytics in the 18th and 19th centuries. J. H. Lambert introduced a variety of improvements in cartography. William Playfair is generally credited with pioneering several visual techniques including the pie chart, the bar chart, and the time-series line graph. Joseph Priestly popularized the time line. Florence Nightingale, in the mid-1800s, brought data visualization into policy-making circles through her advocacy for public health and sanitation. John Snow similarly demonstrated the importance of data visualization to medicine and public health, identifying the waterborne nature of cholera by plotting data from a London outbreak. In spite of these advances, until the early 20th century, data visualization primarily remained a tool of academics and elites. Early visualizations were hand-drawn, making them costly and time-consuming to produce. However, the expansion of print and audiovisual media and, later, computing technology expanded the reach of visualizations and the capacity to produce them. Such advances significantly lowered costs and barriers to entry.

Guiding Principles

Best Practices

Knowing the history of the field, it is relevant to ask why visualizations matter and under what conditions researchers should use them. Visualizations usually aim to produce impact and can be used either in idea generation (like the observation of trends or the mapping of concepts) or the presentation of results. Experts in the field of data analysis generally agree on a number of features characteristic of good visualizations. These include accuracy and honesty in representing data, clarity in telling a story, parsimoniousness in the

sense of avoiding busyness and clutter, and integration with the substance of the paper or report. An important consideration resulting from these criteria is that visualizations aren't always the best means for presenting data. Where a table or text would suffice, or where a visualization cannot be produced with sufficient quality, visualizations may obfuscate relationships rather than illuminating them.

Individuals interested in data visualization can find a wealth of resources devoted to design issues. However, additional practical considerations apply where researchers hope to publish visualizations as part of their findings. Publishing standards in the academic realm vary with regard to images. Although electronic publishing is widespread, publishers may still be sensitive to the cost of printing images. As a result, the number or type of visualizations an author can include in published material may be limited. Some publishers may pass the cost of printing images (especially color images) on to authors, while others will count them against overall word limits. These restrictions can cause frustration. Statistician Edward Tufte took out a mortgage on his home to self-publish his canonical work, *The Visual Display of Quantitative Information*, in 1982 after commercial publishers were unable to meet his vision. Fortunately, today's scholars have other avenues available to circumvent such restrictions. Hosting visualizations through a publisher's website as online appendices is one alternative, as is hosting visualizations on one's own website or sharing them through social media and blogs. Several widely used social science data sets—for example, the World Values Survey and WomanStats—host their own visualizations on their websites and provide researchers with tools to generate visualizations using their data. Researchers who envision the need for many and complex visualizations in their research projects may wish to investigate the publication conventions within their field.

Ethics and Accessibility

Scholars use visualizations in their research precisely because they are powerful. Historical examples like those already discussed show how visualizations can be used to persuade readers and provoke or deter actions. Ethical considerations in visualization include honesty in the presentation of data, accessibility in visual presentation, and an understanding of potential impact. Researchers should also be attentive for the potential for bias. As data collection efforts have often underrepresented or misrepresented the experience of marginalized groups in society, responsible visualization requires reflecting on what biases researchers may be reproducing or magnifying through the power of imagery.

A case study of the possibilities and pitfalls for data visualization can be found in the COVID-19 pandemic, which began in 2019 and spread globally during 2020. Data visualization took on urgent importance for governments, institutions, and citizens worldwide as a means to communicate the spread of the novel coronavirus. Some of these efforts were hindered by quality issues and ethical questions. In the U.S. state of Georgia, repeated errors and poor organization in visualizations released by the Department of Health created the misleading impression of an overall reduction in cases when there was no such trend. The enduring nature of the pandemic meant that some organizations updated their visualization designs frequently to incorporate new types of information. The resulting graphics were progressively more intricate and interactive but entailed trade-offs in usability, requiring users to constantly readjust to new presentation formats. The importance of visualizations for public health further sparked important conversations about accessibility, as blind and visually impaired audiences were sometimes left unable to access this information. Responses to this crisis showed the power visualizations can have and should motivate content authors to consider how to use that power responsibly.

Accessibility in data visualization is commonly associated with blindness and visual impairment, although this is not the only instance in which such concerns apply. Mechanical impairments may limit access to interactive visualizations, while cognitive issues can similarly inhibit user experience. Access to interactive and complex visualizations may likewise be limited for those with low computing power or who lack high-speed and reliable internet connections. Best practices for creating accessible visualizations include the use of alternative text to explain graphics, attention to text size, the use of high-contrast colors and defined borders, and the addition of keyboard navigation options to interactive visualizations.

Tools and Training

For the researcher who decides that visualizing data is appropriate for his or her project, a range of options exist for both quantitative and qualitative work. In line with the criteria previously discussed, a researcher's choices among techniques and applications with which to create visualizations may be guided by a number of factors. These include the nature of their research; their level of technical expertise; conventions within their field; and their resources in terms of computing power, time, funding, and assistance. This discussion further assumes that most researchers today will rely on computer-generated visualizations, although, as discussed later, this may not always be the case.

Graduate and undergraduate students in research methods courses will often find certain programs and techniques for data analysis and visualization preferred by their instructors or departments, yet alternative avenues exist for training. Larger universities may have dedicated staff in library and information sciences who can offer consultation or training on an array of programs based on the type of visualization a researcher wishes to produce. Professional associations may offer discipline-specific opportunities like short courses. Online, researchers can also find message boards, training manuals, videos, and websites devoted to training resources. The nonprofit Data Visualization Society hosts a range of resources on its website.

Quantitative Analysis

For quantitative researchers, the classic techniques pioneered by Playfair and his contemporaries—histograms, line graphs, bar charts, pie charts, and so on—remain relevant, widely understood, and easy to produce. Basic word processing and spreadsheet applications, some of which are open-source and available for free online, can produce graphics of sufficient quality for print. More intricate graphics representing complex relationships, statistical analyses, or large amounts of data may require more specialized programs and additional computing power. Popular software packages for statistical analysis and visualization include SAS, SPSS, Stata, and Minitab. Which, if any, of these software packages a researcher uses may be a matter of personal and institutional preference. Each of these applications carries a learning curve, meaning that time, expertise, and availability of instruction may all be considerations. More recently, the licensing costs and limitations of proprietary programs have pushed some to embrace open-source alternatives. The R programming language and software environment is a free and flexible option with a large following devoted toward the creation of specialized packages capable of producing sophisticated analysis and visualization. Various free applications also exist for geographic information systems mapping and network analysis. Finally, an emerging marketplace of low-cost or free commercial applications can be found online for creating maps, infographics, and other visualizations.

Qualitative Analysis

For the qualitative researcher, various options also exist. Popular visualization forms for qualitative research include word clouds, timelines, word trees, dendrograms, flow or path diagrams, and network

maps. Text-as-data approaches allow for the development of numerous types of visualizations that can be generated from interview transcripts, field notes, primary documents, and any other text-based sources. In the case of visual methods, visual or audiovisual materials themselves are the data—posing similar presentation and publication challenges to those encountered by researchers engaged in other forms of complex visualization. Visualization can play important and unexpected roles in qualitative research. For example, Elisabeth Wood's 2003 work on insurgent collective action in El Salvador's civil war (1980–1992) utilizes hand-drawn maps created by local residents to show changes in land ownership, damage during the war, and to demonstrate the power of affect and campesino self-image. Such work again shows the power and the creative potential for visualization as a tool for understanding the world.

DATABASES

This entry discusses two types of databases: databases for literature searches and databases for research data. These two types of databases are those that are most often part of a research process. Databases for literature searches are bibliographic databases, repositories, and information systems that are used to find relevant literature. These databases span the more commonly used digital library catalogs and discovery systems, disciplinary databases such as Education Resources Information Center (ERIC) for educational research, and generic scientific databases and online platforms (e.g., Web of Science, Scopus). Databases for research data can be used to retrieve data sets or collections of materials for research. This includes databases that maintain data collected through international surveys (e.g., Trends in International Mathematics and Science Study), data repositories, and registers that are maintained for administrative or other purposes but can nevertheless be used as sources of research data. To note, the term *database* is used here in a broad sense and refers to a variety of databases, repositories, and systems. The following two sections of this entry provide insight into the two types of databases; the last section points to questions to be asked when choosing a suitable database.

Databases for Literature Searches

There are numerous databases that can be used to search for scholarly literature. All these databases contain bibliographic metadata on scholarly publications—for instance, the title, author, and publication year. Bibliographic databases typically do not contain full-text publications. Instead, they contain links that lead to either the publisher website or some other location where the full-text publication can be purchased and/or accessed. If a bibliographic database contains a full-text publication, it is referred to as *repository*.

Bibliographic databases differ in their scope. Some databases include literature from all areas of research. Others, in contrast, are specialized in literature from a particular academic discipline. Not all areas of research have the same range of information resources. Also, not all databases are freely accessible—some require a subscription that often is arranged at a university level.

Until recently, library catalogs were the main tools used to search for research literature. Since around 1970s, the traditional paper catalogs have been digitized and made available for browsing online. Now in most cases, library collections can be navigated through an

online public access catalog (OPAC) with university libraries being no exception. Universities usually have access to other databases useful for literature searches. These databases can be accessed directly from their websites. Alternatively, databases can be accessed through discovery systems—a more recent trend whereby OPACs are replaced by systems that help to access research from a single website, not just the university library catalog but also the numerous databases to which the university library has access.

When the focus in a literature search is on books and other publications that most likely can be found in a library, a useful source is WorldCat, which is maintained by the Online Computer Library Center (OCLC). WorldCat provides online access to library collections in libraries that are members of the OCLC network. The number of participating libraries exceeds 15,000. A search through the WorldCat user interface can identify the geographically most accessible library where the publication of interest can be found. In addition, WorldCat can help to identify a relevant edition and/or translation, if there are several.

The increasingly popular databases that are used for literature searches are the generic bibliographic and citation databases for scholarly content. Research exploring how students and researchers find their literature shows that Google Scholar is one of the most popular databases. Google Scholar is a freely accessible web search engine that is based on one of the largest databases that indexes scholarly content on the web. Exact information of the scale of this database is not publicly available, but according to estimates, Google Scholar contains metadata on more than 350 million documents. Besides metadata on scholarly publications, Google Scholar also contains information on citations. For example, a search of a specific title will retrieve the title with an option to list all the publications that have cited this title. This can be a useful literature search strategy. It is important, however, to note that the content of this database is collected by web crawlers with limited human intervention. Consequently, not all content that is displayed in search results refers to scholarly publications. Sometimes it contains presentation slides, policy documents, or other texts stored on the web. Therefore, the search results from Google Scholar have to be carefully scrutinized for quality. This is very different from, for example, research library collections that are curated by librarians and scholars and result in reliable collections of scholarly literature. Nevertheless, Google Scholar remains the most accessible comprehensive bibliographic database, especially for scholarly literature in the social sciences and humanities that is less accessible in, for instance, Web of Science.

The Web of Science platform (owned by Clarivate Analytics) is another popular source that can be used for literature searches. This is a subscription-based platform that provides access to multiple databases that index not only metadata of publications but also their citations. The main databases together form the Web of Science Core Collection: Science Citation Index Expanded (SCI-E), Social Sciences Citation Index (SSCI), Arts and Humanities Citation Index (AHCI), Emerging Sources Citation Index (ESCI), Conference Proceedings Citation Index, Book Citation Index, and Current Chemical Reactions and Index Chemicus. Web of Science is one of the oldest generic databases for scholarly literature.

Even though it is generic in scope, it is better suited to some disciplines (e.g., psychology and economics) and not others (e.g., law). This is related to the content collection principles for these databases. For example, four of the indices in Web of Science (SCI-E, SSCI, AHCI, and ESCI) index only journal articles. Besides this, not all journals are included in these databases, and research has shown that the journal selection policy is biased toward English-language journals. In addition, the number of conference proceedings and books indexed in the other two indices is rather low. Consequently, a large part of literature published in languages other than English or in other formats (e.g., book chapters, monographs, conference papers) is not included and therefore is not searchable in Web of Science. Despite the incomplete coverage of publications in the social sciences and humanities, Web of Science is a useful database for literature searches since it offers a user interface with numerous functionalities that help to navigate and interact with the database. Other databases similar to the Web of Science platform are Scopus (owned by Elsevier), Microsoft Academic (Microsoft), and Dimensions (Digital Science). All these databases also include citation data. Other generic bibliographic databases include ScienceDirect, JSTOR, Academic Search, and EBSCO.

Bibliographic databases specialized in scholarly literature in a specific academic discipline are another alternative. Some examples of such databases are the ERIC for educational research, PsycINFO for behavioral and social sciences research, and Sociological Abstracts for sociology and related disciplines. These are curated databases that include metadata of publications and sometimes also full-texts publications. If full text is not provided, a publication record includes information where the full text can be accessed.

An alternative set of resources has emerged in recent decades parallel to the open-access movement that promotes open access to scholarly literature. This has resulted in the implementation of institutional

repositories in universities and other research organizations. These repositories store full-text publications. Sometimes due to restrictions imposed by publishers, only postprints of publications can be archived. This means the only version that can be accessed is the latest authors' version that has been submitted for publication after addressing reviewer comments (i.e., postprint). The publisher version is not available. In addition, publisher can set an embargo, a period of time for which even a postprint cannot be accessed. Consequently, the most recent publications often remain behind a paywall. Despite these limitations, open-access full-text repositories are a rich source for publications, especially if one is searching for work by a specific author or a research group. Besides institutional repositories, there are aggregators that combine content of institutional repositories and provide a single access point. In Europe, such an aggregator is OpenAire, which provides access to more than 57 million open-access publications. Somewhat smaller but nevertheless a valuable access point to open-access publications is the Directory of Open Access Journals (DOAJ). DOAJ contains more than 15,000 journals and nearly 6 million publications.

Similarly, national databases for research output and current research information systems can be used for literature searches. Many such databases are created for research evaluation, funding allocation, and other purposes related to research management and administration. At the same time, a number of these national databases provide a user interface that can be used to search for literature. In Europe, such examples are the Croatian Scientific Bibliography, Current Research Information System in Norway (Cristin), and SwePub in Sweden. These databases, similar to the institutional repositories, are particularly useful when the literature of interest concerns a particular country and/or is authored by researchers working in a particular country. Other databases that can be used for literature searches are preprint servers (e.g., ArXiv, SocArXiv) and databases for theses and dissertations (e.g., Open Access Theses and Dissertations).

Databases for Research Data

There are numerous databases that store data that can be used for research. This includes research data collected by other researchers or organizations and data that are collected for some other purposes but nevertheless can be used in research.

A well-known source of data in educational research is the data repository maintained by the International Association for the Evaluation of Educational Achievement (IEA). This organization has for several

decades conducted large-scale international surveys of student achievement (e.g., Trends in International Mathematics and Science Study, Progress in International Reading Literacy Study). The IEA data repository stores all the collected data along with accompanying documentation that can be freely accessed online and used for research. Other examples are Programme for International Student Assessment administered by the Organisation for Economic Co-operation and Development OECD, International Social Survey Programme for social sciences, and Pew Global Attitudes survey.

Another source of research data are the numerous data repositories and data archives where researchers and research organizations can make their data publicly available for use. For social sciences, a useful source is the Data Catalog maintained by the Consortium of European Social Science Archives (CESSDA) that enables browsing through metadata of more than 30,000 data sources stored in repositories participating in CESSDA. Even though the focus of CESSDA is on Europe, the data made available in the Data Catalog address countries beyond Europe. Another registry of data repositories that can be used to identify a suitable one is the Registry for Research Data Repositories (re3data). Other examples of data repositories are Harvard Dataverse, ReShare (for social sciences), and openICPSR. Besides these, data repositories are often maintained by universities, thus both making available research data from a particular university and also providing an infrastructure for researchers to deposit their data for long-term preservation and access.

Research data can be acquired from databases, registers, and other types of data collections that are not collected for the purpose of research. A type of such data source with the longest history are national and international statistics that are increasingly made publicly available. For example, the vast collections of data gathered by OECD can be browsed and accessed online. Other examples include smaller scale data collections stored by various organizations. Not all these data, however, are readily available for research and often, before using administrative and statistical data for research purposes, a number of ethical and legal requirements have to be met. For example, data that reveal or can lead to the identification of an individual person would require substantial justification of the need of such data. Also, if data have been collected for a purpose other than research, often their use for research purposes is not possible unless additional informed consent is acquired from people who are represented in the data. The same legal and ethical considerations apply for the use of research data in data repositories. Sometimes, even

though data are stored in a repository, they can be accessed only after a negotiation with the researchers who collected the data.

The final point to be highlighted in relation to databases for research data is the importance of metadata and other documentation on data. For successful use of data in research, it is crucial to know who collected the data, how, from whom, and for what purpose. For example, two data sets that store information on reading behavior can differ depending on whether the data were collected in an educational or leisure context. Besides this, one and the same material can be represented as data in different formats. For example, interview transcripts can follow different conventions. Quantitative data variables can be operationalized in numerous ways, hence, the importance of data documentation.

Data documentation, however, cannot cover all the possible questions that are important for the understanding of a particular data source or data set. Research in the field of critical data studies shows that data—quantitative or qualitative—are far from neutral representations of the phenomena they represent or describe. Instead, data carry numerous assumptions both about the phenomena in focus and the ways to scrutinize them in research. Consequently, data sometimes embody various biases that have implications for research. The same applies to absences data. If a data set has systematically missing data on a particular variable or a certain social group is not part of the research sample, this can be an indication of a clash between assumptions by researchers who collected the data and research participants. Information on this, however, rarely will be part of data documentation and therefore requires critical consideration of data, data source, researchers and organizations involved in data collection, and the role they play in a larger societal context.

Choosing a Suitable Database

The number and the range of databases that can be used to search for literature and to access research data might appear overwhelming. The vast and continuously growing number of databases make it indeed increasingly challenging to find a suitable database. Therefore, a good approach is to consult with academics working in the relevant field and institution/country. While in some academic disciplines there are specialized databases for literature, in other disciplines the generic databases are the best choice. All data sources do not include literature from all countries in the world, or they can be limited to a particular language (e.g., English). In addition, universities

typically have access only to a selection of databases. The same applies to databases for research data. Similarly, in some disciplines, the use of research data from data repositories and statistical data collections is a common practice; in other disciplines, it is very rare. Due to these differences, university tutors and other academic staff are best positioned to point out which databases could be of best use. Besides, advice can be asked to university library staff who, firstly, can provide an overview of relevant databases that can be accessed and, secondly, can also help with navigating the sometimes confusing database user interfaces, finding the most suitable search criteria, or with the interpretation of search results.

DEBRIEFING

Debriefing is the process of giving participants further information about a study in which they participated at the conclusion of their participation. Debriefing continues the informational process that began with

participant recruitment and informed consent. During debriefing, participants are reminded of the purpose and importance of the study, given further information about expected results, and thanked for their participation. Debriefing thus serves an educational purpose; participants may learn more about the value of their participation in research and their contribution to scientific understanding. The debriefing process also provides an opportunity for participants to ask questions of the researcher. This entry discusses the purpose of debriefing, the debriefing process, and types of debriefing. It then looks at the ethical considerations surrounding debriefing, debriefing in internet research, and debriefing with child participants.

In some research situations, participants are asked to discuss negative emotions or reveal sensitive information (e.g., studies on mental illness or sexual behavior). In such studies, the researcher may incorporate information about how participants might obtain help in dealing with these issues, such as a referral to a campus mental health center or crisis hotline, into the debriefing process.

If a study includes deception, debriefing is more complex. In such instances, a researcher has concluded that informing participants of the true purpose of the study at the stage of obtaining consent will interfere with the collection of valid and generalizable data. In such instances, the researcher may give participants incomplete or misleading information about the nature of the study at the recruitment and consent stages. Other examples of deception in social science research include deceptive instructions, false feedback, or the use of confederates (members of the research team who misrepresent their identities as part of the study procedure).

In a deception study, the debriefing session is the time when a complete explanation of the study is given and the deception is revealed. Participants should be informed of the deception that took place, the true purpose of the research, and the reasons why the researcher believed deception was necessary. As in a nondeception study, participants should be thanked for their participation and provided with an opportunity to ask questions of the researcher. Participants should also be reminded of their right to withdraw from the study at any time. This reminder may take various forms, ranging from the inclusion of a statement in the debriefing script indicating participants' ability to withdraw to having participants sign a second informed consent form after being debriefed.

The Debriefing Process

David Holmes has argued that debriefing should include processes of *dehoaxing* (if necessary) and *desensitizing*.

Dehoaxing involves informing participants about any deception that was used in the study and explaining the researcher's rationale for the use of deception. Desensitizing involves discussing and attempting to diminish any negative feelings (such as stress or anxiety) that may have arisen as a result of the research process.

Negative feelings may result from the research process for various reasons. The purpose of the research may have been to study these feelings, and thus researchers may have deliberately instigated them in participants. For example, researchers interested in the effects of mood on problem-solving might ask participants to watch a sad film clip before completing a problem-solving task. Negative feelings may also arise as a consequence of engaging in the behavior that researchers were interested in studying. For example, researchers interested in conformity and compliance to authority may create situations in which participants are expected to engage in behavior with which they are uncomfortable (such as administering punishment to a confederate). In such a situation, a researcher might address possible negative feelings by stating that the participant's behavior was not unusual or extreme (e.g., by stating that many other participants have acted the same way). Another approach is to emphasize that the behavior was due to situational factors rather than personal characteristics. Desensitizing may encourage participants to make an external (situational) rather than an internal (personal) attribution for their behavior. Participants may feel angry or embarrassed about having been deceived by the researcher. One desensitizing technique applicable to such situations is to point out that negative feelings are a natural and expected outcome of the study situation.

Joan Seiber states that participation in research and postresearch debriefing should provide participants with new insight into the topic of research and a feeling of satisfaction in having contributed to scientific understanding. Seiber states that participants should receive a number of additional benefits from the debriefing at the conclusion of a deceptive study: dehoaxing, desensitizing, restoration of confidence in scientific research, and information on the ways in which possible harm has been anticipated and avoided. Seiber also states that the dehoaxing process should include a convincing demonstration of the deception (e.g., showing participants two identical completed tasks, one with positive feedback and one with negative feedback).

Types of Debriefing

There are several types of debriefing associated with deception studies. In each type, the researcher describes

the deceptive research processes, explains the reasons why research is conducted on this topic and why deception was deemed necessary to conduct the research, and thanks the participant for his or her assistance in conducting the research.

An *explicit* or *outcome debriefing* focuses on revealing the deception included in the study by describing the deceptive processes used. Explicit debriefing might also include a concrete demonstration of the deception, such as demonstrating how feedback was manipulated or introducing the participant to the confederate.

A *process debriefing* is typically more involved than an explicit debriefing and allows for more opportunities for participants to discuss their feelings about participation and reach their own conclusions regarding the study. A process debriefing might include a discussion of whether the participant found anything unusual about the research situation. The researcher might then introduce information about deceptive elements of the research study, such as false feedback or the use of confederates. Some process debriefings attempt to lead the participant to a realization of the deception on his or her own, before it is explicitly explained by the researcher. A somewhat less common type of debriefing is an *action debriefing*, which includes an explicit debriefing along with a reenactment of the study procedure or task.

Ethical Considerations

Ethical considerations with any research project typically include an examination of the predicted costs (e.g., potential harms) and benefits of the study, with the condition that research should not be conducted unless predicted benefits significantly outweigh potential harms. One concern expressed by ethicists is that the individuals who bear the risks of research participation (study participants) are often not the recipients of the study's benefits. Debriefing has the potential to ameliorate costs (by decreasing discomfort and negative emotional reactions) and increase benefits (by giving participants a fuller understanding of the importance of the research question being examined and thus increasing the educational value of participation).

Some experts believe that debriefing cannot be conducted in such a way as to make deception research ethical, since deceptive research practices eliminate the possibility for truly informed consent. Diana Baumrind has argued that debriefing is insufficient to remediate the potential harm caused by deception and that research involving intentional deception is thus unethical and should not be conducted. Other

arguments against debriefing after deception include the potential for debriefing to exacerbate harm by emphasizing the deceptiveness of researchers or for participants to disbelieve the debriefing, inferring that it is still part of the experimental manipulation.

Other experts have argued that it is possible to conduct deception research ethically but have expressed concerns regarding possible negative outcomes of such research. One such concern regarding deception and debriefing is the *perseverance phenomenon*, in which participants continue to believe or be affected by false information presented in a study after debriefing. The most prominent study of the perseverance phenomenon was conducted by Lee Ross, Mark Lepper, and Michael Hubbard who were interested in adolescents' responses to randomly assigned feedback regarding their performance on a decision-making task. At the end of the study session, participants participated in a debriefing session in which they learned that the feedback they had received was unrelated to their actual performance. Ross and colleagues found that participants' self-views were affected by the feedback even after the debriefing. When participants were explicitly told about the perseverance phenomenon as part of the debriefing process, their self-views did not continue to be affected after the debriefing. This example demonstrates the importance of a thoughtful approach to debriefing that addresses the possible harms specific to a given research project.

The American Psychological Association's (APA) *Ethical Principles of Psychologists and Code of Conduct* states that debriefing should be an opportunity for participants to receive appropriate information about a study's aims and conclusions and should include correction of any participant misperceptions of which the researchers are aware. The APA's ethics code also states that if information must be withheld for scientific or humanitarian reasons, researchers should take adequate measures to reduce the risk of harm and address any harm that does occur.

Debriefing in Internet Research

The majority of research and policy on debriefing in experimental research is based in assumptions that research takes place in a laboratory setting. However, debriefing may also be necessary in other research contexts such as internet-based research. In internet-based research, debriefing is typically presented in the form of a debriefing statement as the final screen of the study questionnaire or as an email sent to participants. One challenge to appropriate debriefing in internet-based research is withdrawal from the study. If

participants do not complete participation in an online study, the cause of this termination may be unclear to the researcher (e.g., termination may have been due to discomfort with the study procedure or simply a loss of internet connection). Thus, researchers should consider strategies for providing debriefing to all participants including those who terminate participation before the completion of the study.

Recently, scholars have questioned the ethics of internet-based research that involves experimental manipulations of which research participants may not be aware. The most well-known version of such a research project involved modifying individuals' Facebook news feeds to include more positive or negative information and examining the effects on mood. Some researchers criticized this research for neglecting to debrief participants following the experimental manipulation.

Debriefing with Child Participants

In research with children, informed consent prior to participation is obtained from children's parents or guardians; child participants give their assent as well. In studies involving deception of child participants, parents are typically informed of the true nature of the research at the informed consent stage but are asked not to reveal the nature of the research project to their children prior to participation in the study. After study participation, children participate in a debriefing session with the researcher (and sometimes with a parent or guardian as well). In this session, the researcher explains the nature of and reasons for the deception in age-appropriate language.

Marion Underwood has advocated for the use of a process debriefing with children. Underwood also argues that it is important for the deception and debriefing to take place within a larger context of positive interactions. For example, children might engage in an enjoyable play session with a child confederate after being debriefed about the confederate's role in an earlier interaction.

DECEPTION

Deception entails the intentional distortion or omission of information in order to cause someone to entertain a false belief. In research settings, deception is commonly employed when it is believed that a full disclosure of the true nature of a study would alter the phenomena under investigation, thereby invalidating the results. For this reason, deception is especially common in research domains such as experimental psychology and cognitive neurosciences. However, the use of deception in research raises a host of ethical issues, as it typically infringes participants' right to informed consent, autonomy, and trust. Against this background, this entry outlines the main scientific and ethical arguments pertaining to deception in research. The first section introduces the scientific rationale for deception in research

settings. Then the second and third sections provide an overview of the main ethical arguments related to the use of deception in research. The fourth section presents two methods that can mitigate the ethical impact of deception in research: debriefing participants at the end of the research and providing them with the option of withdrawing the data from the study. Next, the fifth section clarifies researchers' ethical obligations to accurately report deception in published research. The entry concludes by exploring the possibility of adopting an alternative paradigm of *authorized deception*.

Deception in Research: Scientific Rationale

Before enrolling in research, all competent adult participants must provide their valid informed consent. In order to do so, they must be truthfully and adequately informed about the main features of the study in which they will partake. Such information typically includes a disclosure of the scientific aims of study, of the research design and methods adopted, and of the risks involved. Sometimes, however, a transparent disclosure of such information may conflict with the purpose of obtaining valid scientific knowledge. Informing the participants that a study will assess their attitudes toward cheating or lying, for instance, would likely alter their behavior, thus invalidating the experiment. Likewise, informing the participants that a study will investigate the role of expectations in pain perception would likely result in influencing such expectations, biasing the study. In general, truthful disclosures for the sake of informed consent may be problematic in many experimental studies investigating cognitively mediated phenomena such as human perception, sensation, attitudes, behaviors, interpretations, or beliefs. When the provision of a standard disclosure for informed consent is believed to be incompatible with the scientific aim of a study, the experimenters may consider adopting a deceptive research design. In a deceptive research design, participants are deliberately misled or not informed about salient aspects of the study. For instance, they may be misled about the true aim of the study, the nature of the interventions they receive, the role played by researchers and research assistants, or the tasks they are required to perform. All these forms of strategic deception are meant to preserve the internal validity of a study by manipulating the information available to the participants before and during the experiment. For certain investigations of important questions in psychology and neurosciences, strategic deception may be the only option to obtain scientifically valid results.

Deception and Informed Consent

The use of deception in research is ethically problematic. On the one hand, deception may be needed to preserve the scientific validity of a study. On the other hand, deception raises important ethical issues. First, as previously noted, the use of deception entails that research subjects are not fully or truthfully informed about salient aspects of the study in which they participate. Hence, deception is incompatible with the standard process of obtaining informed consent. In order to conduct a deceptive study, researchers must first obtain permission to alter or waive the standard requirement of informed consent from an ethics committee (EC) or institutional review board (IRB). In general, four conditions must be satisfied in order to grant the permission to alter or waive the requirement of informed consent: (i) the proposed study must be scientifically sound; (ii) the study involves no more than minimal risks for participants; (iii) the study cannot be performed without deception; and (iv) whenever possible, the subjects will be appropriately informed at the end of the study. If these conditions are met, a study may be ethically approved even though it is deceptive.

Deception, Autonomy, and Trust

In addition to informed consent, two other ethical rationales must be carefully considered while designing and conducting a deceptive study. These other rationales relate to the broader ethical consequences of deception in research contexts and are crucial to guide researchers in designing and implementing ethically adequate mitigating strategies. The first rationale concerns the respect of participants' autonomy. In general, autonomy can be defined as the capacity to decide and act according to a self-chosen plan free from controlling influence by others. Specifically, the general duty of respecting participants' autonomy can be understood as the conjunction of two more specific obligations. One is the duty of not infringing on participants' *liberty* by forcing or coercing them to participate in research. The other is the duty of respecting and fostering participants' *agency* by providing them all relevant information to make autonomous choices. Note that, on this view, the omission of salient information may be as morally problematic as open deception, as in both cases one would equally fail to respect participants' agency. Therefore, to some extent, any deceptive study always infringes on participants' autonomy.

The other rationale, instead, concerns trust. In science, trust is essential to ensure that people volunteer

for research. Without a minimal threshold of trust, in fact, the only option to advance scientific research would be to resort to coercion or force, a clearly unethical option. In part, a trusting attitude toward volunteering in scientific research is based on the belief that research participants will not be exploited by researchers or exposed to significant risks without their consent. Deceptive studies, however, may cast a legitimate doubt about the respect of such fundamental ethical obligations by researchers and the scientific community. Accordingly, deceptive studies may compromise individual and public trust in science, potentially impairing scientific progress. This may be especially problematic in biomedicine, where a breach of trust may additionally translate into negative consequences at the levels of individual and public health, as people may become more suspicious about what doctors and other experts recommend.

Deception, Debriefing, and Data Withdrawal

To cope with the ethical implications of deception in research, investigators should plan and implement mitigating strategies at the end of the study. As previously noted, altering or waiving the requirement of informed consent requires meeting certain conditions, one of which mandates that all participants should be adequately informed at the end of the study. Such information disclosure usually occurs at the completion of the research when researchers finally inform the participants about the true nature of the study and the use of strategic omission and/or deception during the experiment. Usually debriefing involves a structured disclosure procedure for participants; depending on the study, it may entail a research assistant reading a script, a phone call, or a contact via email. By disclosing the use of strategic omission/deception during the experiment, debriefing ensures that no scientific research is conducted without eventually informing the research subjects. Debriefing does not aim at adding data to the study, but at preserving trust and avoiding undue exploitation.

Yet, while debriefing may aid in achieving these goals, it still cannot cancel the infringement of participants' autonomy. Informing someone about a deception that has already occurred, in fact, does not provide any actionable way of compensating for the preceding loss of agency. For this reason, in deceptive studies debriefing should be coupled with the possibility for participants to withdraw their data from the study. The option of data withdrawal allows participants to partially restore, although in a post hoc way, their autonomy by shifting back to them the decision on whether deceptively obtained data can be used for

research. Furthermore, it also ensures that people do not contribute to studies in which they would have not participated had they known the truth in advance. In sum, researchers seeking ethical approval for a deceptive study should detail in advance when and how they intend to debrief research participants and whether or not data withdrawal is offered as an option. In case it is anticipated that it will not be feasible to debrief all participants, or to offer data withdrawal, researchers should provide a convincing rationale for such decisions as part of their application to obtain ethical approval from competent ECs or IRBs.

Deception and Research Integrity in Published Research

Researchers have an ethical duty of truthfully and accurately reporting the methodology of their studies in scientific publications. However, the way in which articles report the use of deception in research often lacks transparency. In particular, it is important to stress that in reference to deceptive studies, it is misleading for research reports to declare that all participants "have provided informed consent." As previously noted, deceptive studies are structurally incompatible with obtaining valid informed consent. Therefore, in the absence of specific qualifications, declaring that "all participants" in a deceptive research "have provided their informed consent" represents a misleading (if not wrongful) way of reporting the scientific methodology of the study. To avoid confusion and possible allegations of research misconduct, researchers reporting the results of deceptive studies in scientific publications should include an explicit description of the following: how and why the research included elements of deception how the consent process deviated from the standard elements of informed consent whether these alterations received approval by an EC or IRB the procedure implemented for debriefing and whether participants were given the opportunity to withdraw their data. Such information should ideally be part of the main text of a scientific publication or, in case of space limitations, be provided with the supplementary materials.

Informed Consent and Authorized Deception

A possible alternative to the standard waiving of informed consent is that of adopting a research design based on "authorized deception." In authorized deception disclosures, prospective participants are truthfully informed that some statements about the research design

of the study might be inaccurate or misleading, that such omissions or inaccuracies are needed to preserve the validity of the experiment, that such procedure has been already reviewed and approved by an EC or IRB, and that they will receive a complete disclosure at the end of the study. While authorized deception disclosures still fall short of full informed consent, they provide prospective participants with the opportunity of deciding autonomously whether they want to participate in a study with deception. Thus, other things being equal, adopting an “authorized deception” approach may allow researchers to preserve the validity of a study while minimizing the ethical impact of deception. Nonetheless, like in all other cases in which a full informed consent is not provided prior to the study, researchers employing an authorized deception design ought to receive ethical approval for the study from a EC or IRB, debrief participants at the end of the study, provide the option for data withdrawal, and accurately describe the use of authorized deception in the scientific publications reporting the study findings.

DECISION RULE

In the context of statistical hypothesis testing, decision rule refers to the rule that specifies how to choose between two (or more) competing hypotheses about the observed data. A decision rule specifies the statistical parameter of interest, the test statistic to calculate, and how to use the test statistic to choose among the various hypotheses about the data. More broadly, in the context of statistical decision theory, a decision rule can be thought of as a procedure for making rational choices given uncertain information.

The choice of a decision rule depends, among other things, on the nature of the data, what one needs to decide about the data, and at what level of significance. For instance, decision rules used for normally distributed (or Gaussian) data are generally not appropriate for non-Gaussian data. Similarly, decision rules used for determining the 95% confidence interval of the sample mean will be different from the rules appropriate for binary decisions, such as determining whether the sample mean is greater than a prespecified mean value at a given significance level. As a practical matter, even for a given decision about a given data set, there is no unique, universally acceptable decision rule but rather many possible principled rules.

There are two main statistical approaches to picking the most appropriate decision rule for a given decision. The classical, or *frequentist*, approach is the one encountered in most textbooks on statistics and the one used by most researchers in their data analyses. This approach is generally quite adequate for most types of data analysis. The *Bayesian* approach is still widely considered esoteric, but one that an advanced researcher should become familiar with, as this approach is becoming increasingly common in advanced data analysis and complex decision making.

Decision Rules in Classical Hypothesis Testing

Suppose one needs to decide whether a new brand of bovine growth hormone increases the body weight of cattle beyond the known average value of μ kilograms. The observed data consist of body weight measurements from a sample of cattle treated with the hormone. The default explanation for the data, or the *null hypothesis*, is that there is no effect: the mean weight of the treated sample is no greater than the nominal mean μ . The *alternative hypothesis* is that the mean weight of the treated sample is greater than μ .

The decision rule specifies how to decide which of the two hypotheses to accept, given the data. In the

present case, one may calculate the t statistic, determine the *critical value* of t at the desired level of significance (such as .05), and accept the alternative hypothesis if the t value based on the data exceeds the critical value and reject it otherwise. If the sample is sufficiently large and Gaussian, one might use a similar decision rule with a different test statistic, the z score. Alternatively, one may choose between the hypotheses based on the p value rather than the critical value.

Such case-specific variations notwithstanding, what all frequentist decision rules have in common is that they arrive at a decision ultimately by comparing some statistic of the observed data against a theoretical standard, such as the sampling distribution of the statistic, and determine how likely the observed data are under the various competing hypotheses.

Conceptual quibbles about this view of probability aside, this approach is entirely adequate for a vast majority of practical purposes in research. But for more complex decisions in which a variety of factors and their attendant uncertainties have to be considered, frequentist decision rules are often too limiting.

Bayesian Decision Rules

Suppose, in the aforementioned example, that the effectiveness of the hormone for various breeds of cattle in the sample, and the relative frequencies of the breeds, is known. How should one use this *prior distribution* of hormone effectiveness to choose between the two hypotheses? Frequentist decision rules are not well suited to handle such decisions; Bayesian decision rules are.

Essentially, Bayesian decision rules use Bayes's law of conditional probability to compute a *posterior distribution* based on the observed data and the appropriate prior distribution. In the case of the above example, this amounts to revising one's belief about the body weight of the treated cattle based on the observed data and the prior distribution. The null hypothesis is rejected if the *posterior probability* is less than the user-defined significance level.

One of the more obvious advantages of Bayesian decision making, in addition to the many subtler ones, is that Bayesian decision rules can be readily elaborated to allow any number of additional considerations underlying a complex decision. For instance, if the larger decision at hand in the above example is whether to market the hormone, one must consider additional factors, such as the projected profits, possible lawsuits, and costs of manufacturing and distribution. Complex decisions of this sort are becoming increasingly common in behavioral, economic, and social research. Bayesian decision rules offer a statistically optimal method for making such decisions.

It should be noted that when only the sample data are considered and all other factors, including prior distributions, are left out, Bayesian decision rules can lead to decisions equivalent to and even identical to the corresponding frequentist rules. This superficial similarity between the two approaches notwithstanding, Bayesian decision rules are not simply a more elaborate version of frequentist rules. The differences between the two approaches are profound and reflect longstanding debates about the nature of probability. For the researcher, on the other hand, the choice between the two approaches should be less a matter of adherence to any given orthodoxy and more about the nature of the decision at hand.

DECLARATION OF HELSINKI

The Declaration of Helsinki is a formal statement of ethical principles published by the World Medical Association (WMA) to guide the protection of human participants in medical research. The Helsinki Declaration is not a legally binding document but has served as a foundation for national and regional laws governing medical research across the world. Although not without its controversies, the declaration has served as a standard in medical research ethics since its establishment in 1964. This entry provides a brief review of the history of the Helsinki Declaration and then offers summaries of each section of the seventh revision of the declaration.

History and Current Status

Before World War II, no formal international statement of ethical principles to guide research with human participants existed, leaving researchers to rely on organizational, regional, or national policies or their

own personal ethical guidelines. After atrocities were found to have been committed by Nazi medical researchers using involuntary, unprotected participants drawn from concentration camps, the 1947 Nuremberg Code was established. This was followed in 1948 by the WMA's Declaration of Geneva, a statement of ethical duties for physicians. Both documents influenced the development of the Declaration of Helsinki, first adopted in 1964 by the WMA. The initial declaration, 11 paragraphs in length, focused on clinical research trials. Notably, it relaxed conditions for consent for participation, changing the Nuremberg requirement that consent is "absolutely essential" to instead urge consent "if at all possible" but to allow for proxy consent, such as from a legal guardian, in some instances.

The declaration has been revised seven times. The first revision, adopted in 1975, expanded the declaration considerably, nearly doubling its length, increasing its depth, updating its terminology, and adding concepts such as oversight by an independent committee. The second (1983) and third (1989) revisions were comparatively minor, primarily involving clarifications and updates in terminology. The fourth (1996) revision also was minor in scope but notably added a phrase that effectively precluded the use of inert placebos when a particular standard of care exists.

The fifth (2000) revision was extensive and controversial. In the years leading up to the revision, concerns were raised about the apparent use of relaxed ethical standards for clinical trials in developing countries, including the use of placebos in HIV trials conducted in sub-Saharan Africa. Debate ensued about revisions to the declaration, with some arguing for stronger language and commentary addressing clinical trials and others proposing to limit the document to basic guiding principles. Although consensus was not reached, the WMA approved a revision that restructured the document and expanded its scope.

Among the more controversial aspects of the fifth revision was the implication that standards of medical care in developed countries should apply to any research with humans, including that conducted in developing countries. The opposing view held that when risk of harm is low and there are no local standards of care (as is often the case in developing countries), placebo-controlled trials are ethically acceptable, especially given their potential benefits for future patients. Debate has continued on these issues, and cross-national divisions have emerged. The U.S. Food and Drug Administration (FDA) rejected the fifth and subsequent revisions due to its restrictions on the use of placebo conditions, replacing it with the

Good Clinical Practice guidelines, an alternative internationally sanctioned ethics guide. Ethical guidelines for researchers published by the European Commission, in contrast, continue to refer to the declaration and direct researchers to the WMA for updated information.

The sixth revision of the declaration, approved by the WMA in 2008, introduced relatively minor clarifications. The revision reinforces the declaration's long-held emphasis on prioritizing the rights of individual research participants above all other interests. Public debate following the revision was not nearly as contentious as had been the case with previous revisions. Finally, the seventh revision was adopted in 2013, after a worldwide consultation process lasting 2 years. This update improved readability by placing vital principles under separate subheadings that emphasize the distinctions between them.

In addition to several minor clarifications, substantive changes were made in the seventh revision that reflect an increasing emphasis on social and distributive justice concerns. These include adding a requirement for compensation and treatment for participants who sustain research-related injuries; clarifying the declaration's opposition to the use of placebo-controlled trials; emphasizing that research with a vulnerable group is only justified if the group stands to benefit from the research; and stressing the importance of ensuring access by all participants to the interventions for which efficacy is demonstrated. The seventh revision also places greater emphasis than did earlier revisions on the need to disseminate research results, including studies that yield negative or null findings. It is also more relevant than earlier versions to research undertaken in settings with limited resources (e.g., in resource-poor countries).

Synopsis of the Seventh Revision

The Declaration of Helsinki's seventh revision is comprised of 12 sections and is 37 paragraphs ("articles") long.

Preamble (Paragraphs 1–2)

The preamble defines the declaration as a statement of ethical principles for medical research with humans (including human materials or identifiable information) intended for physicians and others who conduct medical research. It also asserts that the declaration should be considered as a whole, and that its paragraphs should not be considered in isolation but with reference to all pertinent paragraphs.

General Principles (3–15)

The next section outlines general ethical principles that guide research on human participants. These begin with a reminder of the words from the WMA's Declaration of Geneva to which physicians are bound: "The health of my patient will be my first consideration." This idea is soon expanded with an assertion that when research is conducted, the welfare of the participants takes precedence over the more general welfare of science, research, and the general population. This section describes the goals of medical research as better understanding the causes and course of diseases and improving their prevention, diagnosis, and safe treatment. It reinforces that research must encourage the protection of the health and rights of people, noting that the responsibility for their protection rests with the physician or other health-care professionals and never with the participants themselves.

A subsequent paragraph stresses the importance of considering ethical, legal, and regularity norms at local, national, and international levels, while noting that none of these should undermine or compromise any protections set forth in the declaration. Minimizing possible harm to the environment is also mentioned, as is the importance of ensuring that researchers have appropriate training and qualifications. Finally, this section notes that underrepresented groups should be provided appropriate access to research participation, that combining research with medical care is only justified by its health value and assurance of no adverse effects stemming from participation, and that appropriate compensation and treatment is required for participants who are harmed as a result of their research participation.

Risks, Burdens, and Benefits (16–18)

Three paragraphs address risks, burdens, and benefits of medical research. The first stresses that research with human participants is only permissible when the importance of the research objective outweighs the risks and burdens associated with it. The second notes that a careful assessment of predictable risks and burdens for participants must precede all medical research, weighed against the potential benefits, with measures taken to minimize, monitor, assess, and document risks. The third states that a study cannot commence unless physicians are confident they have adequately assessed and can manage the risks, and that when risks are found to outweigh potential benefits or when definitive outcomes have been conclusively proven, physicians must assess whether to continue, change, or stop the study.

Vulnerable Groups and Individuals (19–20)

This section stresses the importance of providing special protections for vulnerable participants who may have an increased likelihood of experiencing harm. It also notes that research with vulnerable participants is only justified when it responds to the health needs and priorities of this group, when this group stands to benefit from what is learned in the search, and when the research cannot be carried out with participants who are not vulnerable.

Scientific Requirements and Research Protocols (21–22)

The first paragraph in this section notes that generally accepted scientific principles and a thorough knowledge of relevant research literature and research methods are prerequisites for conducting medical research. Respect for the welfare of animals is also listed as an expectation. The second paragraph stresses the importance of clearly describing and justifying the research design in a well-articulated research protocol, which should include a statement of ethical considerations (including how principles in the declaration are addressed), as well as information regarding funding, sponsors, affiliations, potential conflicts of interests, participation incentives, plans to treat and compensate participants who are harmed, and post-trial provisions for participants in clinical trials.

Research Ethics Committees (23)

The role of ethics committees is addressed in this section. Research protocols must be submitted to a research ethics committee before research begins, and the committee must be independent, transparent, qualified, and immune from undue influence. The committee must account for relevant laws and regulations while adhering to the protections outlined in the declaration. The committee must also oversee monitoring of ongoing studies, especially where adverse events occur, and must receive a final study report from the researchers that summarizes the study's results.

Privacy and Confidentiality (24)

This section contains one brief sentence stressing the importance of protecting participants' privacy and keeping their personal information confidential.

Informed Consent (25–32)

This section addresses physician responsibilities regarding informed consent and participant understanding

of informed consent in medical research. It begins by stressing the importance of voluntary participation in medical research and the necessity to obtain informed consent for every participant in a medical research study. Next, it describes the information requirements of the consent process, including aims, sources of funding, any possible conflicts of interest, potential benefits, risks, and discomforts of the study, and the participant's right to withdraw consent or refuse to participate. It also urges physicians to obtain informed consent in writing or through nonwritten appropriate documentation and notes that participants also need to be made aware of how they can gain access to the general results of the study.

The third paragraph in this section cautions the physician to seek informed consent for research study participation from individuals who are not in a dependent relationship with the physician. The declaration proceeds to state the importance of participants seeking informed consent from a legally authorized representative if a participant is incapable of providing informed consent. Furthermore, the research conducted with these participants needs to involve minimal risk and minimal burden, as well as no individual benefit unless the benefit is aimed to promote the well-being of the group represented by the participant.

The text then notes that physicians must seek both assent (when able) from participants who are incapable of giving informed consent and consent from the legally authorized representative. The paragraph that follows insists that research with participants who are incapable (physically or mentally) of providing consent should only be conducted when that physical or mental condition is a necessary inclusion criterion of the research study. When that is the case, this paragraph provides recommendations for the next steps: seeking informed consent from the legally authorized representative, and if that is not available, research may continue if the specific scenario has been included in an approved research protocol. As soon as possible, consent must be obtained from the participant or legally authorized representative.

The document then addresses the need to inform participants of the elements of their care that are specific to their participation in the research study. It also emphasizes that a participant's possible decision to refuse participation in a study or withdraw participation cannot have an adverse effect on the relationship between the physician and participant. This section closes by insisting that physicians seek informed consent for the collection and storage of any identifiable human material or data for research purposes.

Use of Placebo (33)

This section highlights the necessity of conducting research on a new intervention against the best available proven intervention. Exceptions to this requirement arise when no proven intervention exists, or the use of no intervention is needed to effectively evaluate the efficacy of the study intervention. In these instances, participants need not be subject to additional risks of harm due to not receiving the best available proven intervention.

Post-Trial Provisions (34)

Prior to conducting a clinical trial, provisions need to be made and secured for participants to receive interventions found to be beneficial during the trial. The information on this process needs to be provided to participants as part of the informed consent.

Research Registration and Public Dissemination of Results (35–36)

This section addresses the requirement of registering research studies in an open public database prior to recruitment of participants. It also stresses adherence to the ethical reporting of results in any publication of the results from studies. All results, whether positive, negative, or inconclusive, must be made publicly available.

Unproven Interventions in Clinical Practice (37)

This final, brief section stresses the importance of following protocol when using an unproven intervention with a patient. Before delivering an unproven intervention, proven effective interventions must either not exist or have been demonstrably ineffective with the patient. Physicians must consult expert advice, obtain informed consent, and offer sound rationale that the unproven intervention offers hope for health benefits to the patient. Upon use, the safety and efficacy of the intervention should be researched and evaluated.

Final Thoughts and Future Revisions

The Declaration of Helsinki remains the world's best-known statement of ethical principles to guide medical research with human participants. Its influence is far-reaching in that it has been codified into the laws that govern medical research in countries across the world. It also has served as a basis for developing other international guidelines governing medical research with human participants. As the declaration has

expanded, it has become more prescriptive and has placed a stronger emphasis on distributive justice and the responsibility of the researchers to protect the vulnerable. It has also generated controversy, and concerns have been raised regarding the future of the declaration, its authority, and its scope.

Future revisions to the declaration may reconsider the utility of prescriptive guidelines rather than limiting its focus to basic principles. Another future challenge will be to harmonize the declaration with other ethical research guidelines, because there often is apparent conflict between aspects of current codes and directives documents. Finally, as a WMA document, the declaration is in many ways narrowly focused on physicians; ideally, other health professionals engaged in medical research will also embrace the principles, abide by them, and build on them.
